root and, on exploration, frank pus was encountered posterior to the aorta. Cardiopulmonary bypass was instituted with topical hypothermia and cold blood potassium cardioplegic arrest of the heart. Aortotomy revealed a deformed bicuspid valve with thickened cusps, extensive inflammation of the whole aortic annulus, and an annular abscess on the posterolateral aspect in the fibrous curtain between the aortic valve and the anterior mitral leaflet related to the commissure between the left coronary and noncoronary cusps. The aortic valve was excised, and the valve ring and abscess cavity were debrided of all friable tissue. A 10-A Starr-Edwards prosthesis was inserted with obliteration of the abscess cavity using interrupted horizontal mattress sutures with subannular pledgets.

The patient came off bypass easily but remained febrile and tachycardic. A murmur developed on the fourth postoperative day, and an echocardiogram revealed a paravalvular leak and a communication between the aorta and the left atrium. The patient became progressively dyspneic and was taken back for operation on the seventh postoperative day. Cardiopulmonary bypass was instituted with femoral arterial and right atrial cannulation. A left ventricular apical vent was inserted and the heart arrested with cold blood cardioplegia given by direct coronary cannulation. Valve dehiscence with extreme disruption of the aortic annulus, especially posteriorly, related to the anterior mitral leaflet was found with a direct communication from the aorta to the left atrium in a paravalvular position. In view of this extreme and persisting infection, tissue destruction, left ventricular-aortic discontinuity and fistula formation, it was decided to avoid prosthetic material and to use a homograft aortic root. A cryopreserved 25-mm homograft aortic root was chosen. The homograft anterior mitral leaflet was used to repair and close off the aorto-left atrial fistula. The homograft aortic root was inserted with coronary artery reimplantation. The patient came off bypass well with minimal inotropic support of adrenalin. He made an uneventful recovery and was discharged after 6 weeks of antibiotic therapy.

Patient 3

A 37-year-old man was referred for prosthetic aortic valve endocarditis with vegetations and a complex posterior aortic root abscess with an aorto-left atrial communication. At age 21 years the patient had porcine aortic xenograft valve replacement for congenital aortic stenosis. This valve degenerated, and when the patient was 28 years old it required replacement by a bovine pericardial xenograft aortic valve. Four years later prosthetic valve endocarditis developed, which necessitated replacement with a St. Jude bileaflet aortic valve prosthesis. The patient was asymptomatic for the next 5 years. Then 6 weeks after a dental procedure with oral penicillin cover, a continuous low-grade fever developed with night sweats and headache. Clinically, splenomegaly and splinter hemorrhages in the nail bed of the toes were noted. On echocardiogram friable vegetations were seen on the aortic valve annulus with a complex posterior aortic root

abscess with aorto-left atrial communication. His blood was sent for culture and sensitivity and the patient was started on a heavy intravenous antibiotic cover. Repeated cultures were sterile, but his fever continued and he was referred in August 1991. In view of the continuous fever, the vegetations on the valve, and the abnormal communication, we decided to operate on him.

The femoral artery and vein were cannulated and midsternotomy performed. Cardiopulmonary bypass was instituted with an additional right atrial cannula for venous return. The heart was arrested by cold blood potassium cardioplegia instilled by direct coronary cannulation after a transverse aortotomy following aortic cross-clamping. The prosthetic valve was found to have friable vegetations on the annulus. The valve was excised. An abscess was found in the posterior part of the aortic root with a small (1 cm × 1 cm) fistula posteriorly below the annulus opening into the left atrium. The abscess cavity and fistula were debrided of all necrotic tissue. A size 22 cryopreserved aortic root homograft was selected with the anterior mitral leaflet attached to it. The homograft anterior mitral leaflet was sutured posteriorly so as to close off the fistula. The valve annulus was then sutured to the aortic root by implantation of the coronary arteries, which had been preserved and mobilized with a 3-mm cuff of surrounding aortic wall. The upper margin of the homograft was trimmed and sewn to the aorta. All the anastomoses were done with continuous 4-0 Prolene (Ethicon, Somerville, NJ). The patient made an uneventful recovery. A postoperative echocardiogram showed a normally functioning aortic valve and no fistula.

Comment

Prosthetic valve replacement for infective endocarditis has been accepted as a standard mode of treatment. There is, however, a tendency for prosthetic valve endocarditis to recur [7]. Mechanical prostheses have the highest rate of infection, homografts the least, and bioprosthetic valves an intermediate risk [8]. Also, in patients with associated aortic root abscess, aortic root destruction, and left ventriculo-aortic discontinuity, simple replacement of the infected prosthesis would not suffice and a more radical operation is required.

Several innovative surgical techniques have been applied to such cases. Symbas and associates [1] reported successful patch closure of the abscess and in situ valve replacement in 1 patient. Reitz and co-workers [2] described a method of translocation of the aortic valve, closure of the native coronary ostia, and saphenous vein bypass grafts to the coronary arteries on 4 patients, with success in 3. Frantz and colleagues [3] used composite prosthesis valve-woven Dacron tube graft reconstruction of the aortic root in 2 patients with success in 1. Kirklin and associates [4] reported successful treatment of 3 patients with infection of an aortic mechanical valve and annular abscess using an aortic valve homograft, the height of the homograft valve sinus being tailored to allow it to cover and exclude the abscess cavity.

Despite the successful results obtained with these tech-

niques, it may not be enough to replace the infected prosthesis and cover over the pus and infected material with pericardial or Dacron patches, as this leaves a pocket of infected material in situ with the risk of recurrence of infection, periprosthetic leak, and dehiscence of the prosthetic valve. Glazier and co-workers [5] have described 30 cases of prosthetic aortic valve endocarditis in which they used a technique of homograft aortic root replacement to avoid these problems. Eighty-one percent of the 21 hospital survivors remained free of major adverse effects (recurrence of endocarditis, need for reoperation, or death).

We have successfully used this technique in 3 patients with prosthetic valve endocarditis, annular abscess, left ventriculo-aortic discontinuity, and an aortic-left atrial fistula in 2 patients (patients 2 and 3). In patient 1, this procedure was required after six previous open cardiac procedures, whereas in patient 3, it was after two previous valve replacements. Conventional methods would most probably not have worked in these patients. The technique of homograft aortic root replacement allows excision of infected and necrotic tissue down to healthy noninfected tissue.

Two of our patients had extensive annular destruction with a fistula into the left atrium in the region of the commissure between the left and noncoronary cusps. The abscess and fistula were excluded from the left ventricle and outflow tract by suturing the leading edge of the anterior leaflet of the mitral valve to the inferior border of the abscess. The superior edge of the abscess was then sewn to the aortic annulus. The coronary arteries were then reimplanted and aortic continuity restored by end-to-end anastomosis of the homograft to the ascending aorta.

The homograft aortic root is a very durable structure, as shown by the results of studies involving large series of patients [9, 10] undergoing aortic root replacement for conditions in addition to prosthetic valve endocarditis, such as relief of various types of left ventricular outflow tract obstruction. The freedom from valve-related death at 5 years was $86\% \pm 6\%$ and freedom from valve-related death at 5 years was $96\% \pm 7\%$ [9]. The probability of freedom from valve failure in the homograft root has been estimated at about 92% at 10 years [11].

The aortic homograft immediately offers excellent hemodynamics of a totally competent valve and restores normal anatomy. This may not always be possible with free-hand homograft valve replacement in patients with distorted anatomy.

We believe that corrective operations in these difficult reoperations for prosthetic valve endocarditis should aim to be curative, radical, and safe, and a homograft aortic root with its inherent properties of durability and resistance to infection seems to be the operation of choice for these patients.

Regulation of Acute Phase Response After Cardiopulmonary Bypass by Immunomodulation

Andreas Markewitz, MD, Eugen Faist, MD, Stephan Lang, Stefan Endres, MD, Lothar Hültner, PhD, and Bruno Reichart, MD

Departments of Cardiac Surgery, General Surgery, and Internal Medicine, University of Munich, and GSF-Institute for Experimental Hematology, Munich, Germany

The object of this prospective, randomized trial was to study the dysregulation effects of cardiopulmonary bypass on the synthesis pattern of interleukin-1, tumor necrosis factor, and interleukin-6, which have been identified as the key mediators of acute phase response. In addition, the counterregulation achieved by administration of indomethacin, which blocks the downregulating mediator prostaglandin E_2 , or indomethacin combined with thymopentin, which enhances T-lymphocytic reactivity, was investigated. Sixty patients who had undergone open heart operations were included in the study. These patients were divided into three groups: group A ($n = 20$) received intravenous indomethacin alone, group B ($n = 20$) received both indomethacin and thymopentin, and group C ($n = 20$) served as control. In control

patients interleukin-1 and tumor necrosis factor synthesis were suppressed postoperatively. This effect was significantly counteracted by indomethacin with no further improvement by adding thymopentin. Interleukin-6 synthesis increased in all groups. Although indomethacin treatment alone had little effect on this phenomenon, additional administration of thymopentin significantly reduced elevated interleukin-6 synthesis. Corresponding differences in clinical outcome could not be detected due to small patient numbers. This study was, however, able to demonstrate that an immunomodulatory therapy can influence alterations in immune mechanisms after cardiopulmonary bypass.

(*Ann Thorac Surg* 1993;55:389-94)

The uniform reaction of the human body to a variety of damage, eg, infections or trauma, is known as "acute phase response." Acute phase response is intended to counteract microbial invasion, localize tissue injury, and clear the body of debris. This is achieved by numerous reactions including activation of the complement cascade and cell-mediated immune system. Clinical symptoms include fever, anorexia, and synthesis of proteases known as acute phase proteins by hepatocytes [1, 2].

Acute phase response commonly results in a complete restoration of the injured tissue. However, if regulation of acute phase response becomes altered, chronic inflammation may be the outcome of too little activation and, in the case of too much activation, death. This dysregulation is caused by a shift in synthesis pattern of substances that mediate acute phase response [1, 2].

In recent years three different agents have been identified as key mediators of acute phase response: interleukin-1 (IL-1), tumor necrosis factor (TNF), and interleukin-6 (IL-6) [1-3]. Interleukin-1 is a cytokine produced mainly by activated immunoregulatory monocytes and macrophages [1-3]. Besides being involved in acute phase response, IL-1 induces production of other cytokines, for example, TNF from macrophages and IL-6 from fibroblasts. In addition, IL-1 represents an essential immuno-

stimulatory agent required for activation of cell-mediated immune response [1, 4, 5].

In many of these effects, IL-1 acts synergistically with TNF, which is produced primarily by macrophages [1, 2, 4, 6]. Tumor necrosis factor enhances production of cytokines, for example, interleukin-2 (IL-2) [4, 7] or IL-6 [2], but needs costimulation by other mediators, for example, IL-1, for this function. Therefore, TNF plays an essential part during activation and regulation of host response [7, 8].

On the other hand, TNF alone or in combination with IL-1 can induce shock [6], and there is evidence that TNF is the major factor responsible for lethal outcome of gram-negative sepsis [9, 10].

Interleukin-6 is another pleiotropic cytokine involved in acute phase response that may cause nearly every symptom of acute phase reaction [2]. It is produced by numerous cells, for example, immunocompetent T and B cells and by macrophages [2]. Interleukin-6 acts synergistically with IL-1 as a costimulator of enhanced T-cell proliferation [2, 5]. On the other hand, IL-6 may have some additional immunosuppressive effects, as IL-6 was found to be elevated in states of depressed immune response [6, 8, 11].

After open heart operations with cardiopulmonary bypass, patients frequently show fever, complement activation, elevated synthesis of acute phase proteins, and other symptoms that may be attributed to an activation of acute phase response [12]. However, instead of an enhanced recovery, patients are susceptible to infections, often

caused by opportunistic microorganisms, which contribute substantially to multiorgan failure [13-15].

These data indicate that there may be a major imbalance within the regulation of acute phase response after cardiopulmonary bypass. The following prospective, randomized study was undertaken to investigate the kind and degree of alteration in synthesis pattern of the key mediators of acute phase response: IL-1, TNF, IL-6 [1-3].

In addition, the study attempted to determine whether immunomodulatory therapy could alleviate the dysregulation of acute phase response. For immunomodulation the cyclooxygenase inhibitor indomethacin, alone or in combination with the thymomimetic drug thymopentin, was used. Indomethacin blocks the synthesis of prostaglandin E₂ (PGE₂) which has been identified as one of the predominant mediators downregulating immune response [8, 16-20]. Therefore, suppression of PGE₂ synthesis by cyclooxygenase inhibition may offset the downregulating effects of PGE₂ on cytokine production.

Thymopentin has the same biological activities as the naturally occurring thymus hormone thymopoietin. It accelerates T-cell activation and T-cell recruitment [21] and may complement indomethacin in restoring or protecting host defense [22]. In a pilot study on cardiac surgical patients, thymopentin administration alone resulted in an encouraging restoration of T-lymphocytic response to antigenic stimulation but failed to restore T-cell receptor expression and cytokine synthesis [23]. Therefore, single-drug administration of thymopentin could not be expected to normalize acute phase response and was not tested.

Patients and Methods

Patient Population

This study was approved by the ethics committee of the Medical Faculty of the University of Munich. From November 1989 to October 1990, a total of 60 patients undergoing open heart operations, all older than 55 years and without evidence of a concomitant malignant or immunologic disease, were included. For the prospec-

tively randomized study they were divided into three subgroups: Group A (n = 20) was given indomethacin (Confortid; Dumex, Copenhagen, Denmark), 100 mg intravenously immediately after operation, and 50 mg three times daily until the fifth postoperative day. Group B patients (n = 20) received, in addition to indomethacin therapy, 50 mg of thymopentin (Timmunox; Cilag, Sulzbach, FRG) subcutaneously 2 hours preoperatively, as well as 48 hours and 96 hours postoperatively. Group C (n = 20) served as control.

All patients were blinded to treatment. There were 45 men and 15 women, who were 63.3 ± 6.8 years old. A total of 46 patients underwent coronary artery bypass grafting and 14 had valve replacement. (For further details see Table 1.)

Anesthesia was induced and maintained with etomidate (200 to 300 µg/kg), fentanyl (20 to 30 µg/kg), and nitrous oxide (50%) in oxygen. If necessary, isoflurane (0.4% to 1.5%) was added. One hundred to 200 µg/kg pancuronium was used as muscle relaxant. Ciprofloxacin (n = 16) and ceftriaxon (n = 44) were used for perioperative antibiotic prophylaxis.

Cardiopulmonary bypass was performed with nonpulsatile roller pumps and disposable bubble (n = 12) or membrane oxygenators (n = 48). The pump was primed with a standard electrolyte solution to which 50 mmol of sodium bicarbonate 8.4% and 2,000,000 U of aprotinin were added. After institution of cardiopulmonary bypass at a flow rate of 2.2 to 2.4 L · m⁻² · min⁻¹, the aorta was cross-clamped and cold crystalloid cardioplegic solution administered (either Kirklin's [n = 44] or Bretschneider's [n = 16] solution). Moderate hypothermia of 28°C was induced. Detailed operative data are listed in Table 2.

No statistical difference could be detected for data of Table 1 and Table 2.

Cell Preparation and Phenotyping

For leukocyte studies, 60 mL of peripheral blood was obtained in sterile heparinized tubes. The blood samples were diluted 1:2 in Hanks' buffered saline solution (Gibco, Grand Island, NY) with 2% penicillin-streptomycin. Pe-

ripheral blood mononuclear cell (PBMC) isolation was carried out immediately by standard Ficoll-Hypaque density gradient centrifugation at 1,500 rpm and 40°C for 35 minutes. After the cells were resuspended with 15% fetal calf serum (Gibco) cell counts were performed with a hemocytometer using 0.1% trypan blue exclusion as a test of viability, which always exceeded 95%. Untreated PBMCs were adjusted to a concentration of 10×10^6 PBMCs/mL.

Interleukin-1 and Tumor Necrosis Factor Assay

Interleukin-1 as well as TNF production in PBMCs was generated by culturing the cell suspension at a cell concentration of 5×10^6 PBMCs in 5-mL culture tubes in the presence of highly purified lipopolysaccharide (*Corynebacterium parvum*; Wellcome Inc, London, UK) at a final concentration of 1 µg/mL at 37°C and 6% carbon dioxide. After 24 hours, supernatants were collected and stored at -80°C until assayed. Interleukin-1 and TNF were measured using a radioimmunoassay for human TNF and IL-1 as previously described [24, 25]. These assays used alloantisera raised in rabbits against the respective human cytokine and radioiodinated cytokine as the tracer.

Interleukin-6 Assay

Peripheral blood mononuclear cells were stimulated with lipopolysaccharide to generate IL-6 synthesis preferentially in monocytes. To generate IL-6 production preferentially in T-lymphocytes PBMCs were cultured at a cell concentration of 4×10^6 PBMCs/mL in the presence of highly purified phytohemagglutinin at a final concentration of 2.5 µg/mL at 37°C and 6% carbon dioxide. After 48 hours, supernatants were collected and stored at -80°C until assayed.

Interleukin-6 was measured employing the MTT assay [26] as described previously [27] using a murine hybridoma cell line (7TD1) that grows only in the presence of IL-6.

Statistical Analysis

Statistical analysis was done with the use of variance analysis and χ^2 test for intergroup analysis. Student's paired *t* test was used for intragroup comparison. A *p* value less than 0.05 was considered significant. The results are expressed as mean ± standard error of the mean, unless otherwise indicated.

Results

Operative Mortality and Morbidity

During the early postoperative period of 30 days, 2 patients died, giving an operative mortality of 3.3%. Both had undergone coronary artery bypass grafting. One patient had been given indomethacin (group A), the other belonged to the control group C. Both died due to septic multiorgan failure, death occurring on postoperative day 10 and day 19, respectively. In both patients pneumonia was the first site of infection to be detected 5 and 4 days before death, respectively. Bacteriologic investigation revealed *Staphylococcus epidermidis* and *Candida albicans* as causative pathogens.

The early morbidity rate was 7% (4/60). One group A patient survived a sepsis that also originated from the lungs. *Staphylococcus epidermidis* was once again identified as the causative microorganism.

Patients who received the combined immunomodulatory therapy produced no evidence of systemic infections. However, one local infection originating from the sternum (day 6) was seen. Another sternum osteitis was found in the control group C (day 9) as well as an aseptic sternal dehiscence (day 16).

No significant difference could be found between the three groups with respect to operative mortality and morbidity.

Immunologic Investigations

INTERLEUKIN-1. The synthesis of IL-1 by PBMCs after lipopolysaccharide challenge decreased in control patients (group C) from a preoperative baseline value of 1.19 ± 0.32 ng/mL to 0.82 ± 0.14 ng/mL on day 1 and remained depressed until the end of the observation period (Fig 1). On day 7, synthesis of IL-1 was 0.78 ± 0.11 ng/mL.

Conversely, in patients treated with indomethacin (group A) there was a substantial increase in IL-1 synthesis on day 1 to 2.66 ± 0.68 ng/mL versus 1.17 ± 0.31 ng/mL preoperatively. On the following days synthesis of IL-1 decreased but remained elevated at 1.86 ± 0.6 ng/mL (day 3), 1.94 ± 0.54 ng/mL (day 5), and 1.93 ± 0.49 ng/mL (day 7).

The additional administration of thymopentin (group B) resulted in nearly the same synthesis pattern of IL-1 as in group A patients. Again an increase in IL-1 synthesis on day 1 to 2.28 ± 0.63 versus 1.1 ± 0.16 ng/mL preopera-

Fig 1. Interleukin-1 synthesis during the first 7 postoperative (p.o.) days after open heart operation (OP) as compared with preoperative baseline values. Data are given for patients receiving indomethacin (A), patients receiving indomethacin combined with thymopentin (B), and controls (C). Dots indicate values that are significantly different comparing groups A and B with control group C.

tively was followed by a decrease in IL-1 on the following days to values still elevated at 1.7 ± 0.3 ng/mL (day 3), 1.62 ± 0.5 ng/mL (day 5), and 1.78 ± 0.6 ng/mL (day 7).

No significant difference were observed when comparing the results within each group. An intergroup comparison, however, showed a significantly higher IL-1 synthesis on day 1 in groups A and B versus group C.

TUMOR NECROSIS FACTOR. The results obtained for this mediator of acute phase response paralleled those found for IL-1 synthesis. Again the results for group C patients (Fig 2) decreased from 1.65 ± 0.17 ng/mL preoperatively to 1.09 ± 0.27 ng/mL on day 1 and remained depressed to 0.91 ± 0.19 ng/mL until day 7.

Administration of indomethacin resulted in a substantial increase in TNF synthesis with a peak on day 1 (2.94 ± 0.74 ng/mL). During the following days TNF synthesis slowly decreased, reaching preoperative baseline values (1.74 ± 0.31 ng/mL) on day 7 (1.61 ± 0.26 ng/mL).

Combined therapy with indomethacin and thymopentin lead to an additional increase in TNF synthesis with a peak on day 1 (3.13 ± 0.77 ng/mL) and day 3 (3.19 ± 0.9 ng/mL). Even at the end of the observation period substantially higher values (2.18 ± 0.57 ng/mL) compared with preoperative baseline values of 1.71 ± 0.3 ng/mL were found.

No significant difference could be found when comparing the values within each group. An intergroup comparison showed a significant higher TNF synthesis for group A and B patients versus group C patients on days 1, 3, and 5 (see Fig 2).

INTERLEUKIN-6. Results of IL-6 synthesis (Fig 3a) differed from those observed in IL-1 and TNF production. All patients showed a substantial increase in IL-6 synthesis by monocytes after lipopolysaccharide challenge, reaching a peak on day 3 (group A, $4,024 \pm 165$ U/mL versus $2,107 \pm 113$ U/mL preoperatively; group B, $2,852 \pm 842$ U/mL versus $1,125 \pm 74$ U/mL preoperatively; group C, $3,508 \pm$

217 U/mL versus $1,533 \pm 63$ U/mL preoperatively), and then slightly decreased until day 7. On day 7, however, IL-6 synthesis was still almost twofold higher compared with preoperative baseline values in all groups (group A, $3,440 \pm 147$ U/mL; group B, $2,207 \pm 226$ U/mL; group C, $2,943 \pm 201$ U/mL).

On each day investigated, group C patients showed the highest and group B patients the lowest increase in IL-6 synthesis whereas group A patients had intermediate results. This is not clearly visible on Figure 3a due to the differences in baseline values. However, no statistically significant difference in intragroup or in intergroup comparison could be detected except for IL-6 synthesis on day 1, which was significantly lower for group B patients compared with group A patients.

Interleukin-6 synthesis after phytohemagglutinin stimulation, ie, synthesis mainly by T-lymphocytes (Fig 3b), showed a pattern similar to that after lipopolysaccharide challenge. Interleukin-6 production increased in all groups with a peak on day 3 (group B, $1,878 \pm 440$ U/mL versus $1,608 \pm 331$ U/mL preoperatively) and day 5 (group A, $2,388 \pm 544$ U/mL versus $1,585 \pm 337$ U/mL preoperatively; group C, $2,544 \pm 557$ U/mL versus $1,507 \pm 303$ U/mL preoperatively). On day 7, IL-6 synthesis was still elevated in group C to $2,356 \pm 475$ U/mL, in group A to $2,107 \pm 486$ U/mL, and in group B to $1,770 \pm 407$ U/mL. During the whole observation period group C patients again showed the highest IL-6 values, whereas the lowest increase in IL-6 synthesis was found in group B patients. These differences gained statistical significance on day 3 and day 5, when IL-6 synthesis in group B was significantly lower than in group C.

Comment

Previous studies have demonstrated that cardiopulmonary bypass, in addition to the operation, alters immunoreactivity, whereas anesthesia has only little effect on host response after a cardiac operation [28, 29]. The question,

Fig 2. Tumor necrosis factor synthesis during the first 7 postoperative (p.o.) days after open heart operation (OP). Dots indicate results that are significantly different comparing groups A and B with control group C.

Fig 3. (a) Interleukin-6 synthesis by monocytes after stimulation with lipopolysaccharide during the first 7 postoperative (p.o.) days after open heart operation (OP). Dot indicates the only result that is significantly different between groups A and B. (b) Interleukin-6 synthesis by T-lymphocytes after stimulation with phytohemagglutinin. Dots indicate the results that are significantly different between groups B and C.

which part of the extracorporeal circulation is responsible for these alterations, cannot be answered with the available data. Most likely, the foreign surfaces of the bypass circuit represent the predominant factor that alters immune response by inappropriate activation [12, 30].

The results of this study suggest that cardiopulmonary bypass results also in an activation of acute phase response: IL-6 is upregulated, IL-1 and TNF synthesis are downregulated in untreated patients (group C). In several animal and other human studies the same changes in synthesis patterns of IL-1, TNF, and IL-6 were found and

related to a depression of host response [8, 11, 31-34]. A downregulation of IL-1 and TNF synthesis has been demonstrated in an animal model of hemorrhaged mice [8]. It was associated with an impaired antigen presentation and major histocompatibility complex class II expression by antigen presenting cells, which are essential for the activation of immune response. These results corroborate the hypothesis that depressed IL-1 and TNF synthesis might have immunosuppressive effects.

Highly elevated IL-6 concentrations are frequently found in patients with burns or infections [6, 31, 32]. The upregulation of IL-6 synthesis in T cells is very likely the result of an intracellular shift from IL-2 synthesis to IL-6 synthesis [11]. Interleukin-1 is known to be downregulated in immunocompromised patients [33]. The decrease in IL-1 synthesis of monocytes has been attributed to an intracellular shift from IL-1 to production of PGE_2 , which is an inhibitor of IL-1 synthesis [34]. Interleukin-1 and IL-2, however, are the two essential cytokines mediating forward regulation of cell-mediated immune response [1, 2]. A depression of IL-1 and IL-2 synthesis therefore implies a suppression of cell-mediated immune response.

All the information and data derived from the present study support the depression of cell-mediated immune response by decreased IL-1 and TNF synthesis. An impaired host response leaves the patient in a partially immunocompromised state that might facilitate infections during the early postoperative course.

The key substance mediating immunosuppressive alterations of host response is PGE_2 , which is known to downregulate IL-1 and TNF synthesis [8, 16, 18-20]. In addition, PGE_2 impairs cell-mediated immune response by reducing, for example, T-cell blastogenesis, IL-2 synthesis, IL-2 receptor expression, and cytotoxicity by activated T cells [17-19]. All these alterations were observed after an adequate operative or accidental trauma had initiated monocytic production of PGE_2 . Prostaglandin E_2 blockade by cyclooxygenase inhibition with indomethacin should counteract PGE_2 -mediated dysregulation of acute phase response. For this reason indomethacin was given after the operation to counteract excessive host response after cardiopulmonary bypass.

Ertel and associates [8] were, in fact, able to demonstrate in an animal study that administration of the cyclooxygenase inhibitor ibuprofen resulted in an upregulation of IL-1 and TNF synthesis and a downregulation of IL-6 production. In our study, administration of the cyclooxygenase inhibitor indomethacin was able to counteract completely the downregulating effects of PGE_2 on IL-1 and TNF synthesis, whereas there was little effect on IL-6 synthesis.

Another agent was therefore required to complete the immunobalancing effects of indomethacin. Because indomethacin contrasuppresses downregulating effects, it seemed sound to add a substance to this treatment that enhances forward regulation, for example, a thymomimetic drug such as thymopentin [21]. The rationale for preoperative administration of thymopentin was to augment host defense mechanisms before operation, as host defense is known to be depressed in elderly patients even without trauma or operation [23, 35]. Interleukin-6 pro-

duction by monocytes and lymphocytes was, in fact, substantially reduced by addition of thymopentin compared with indomethacin alone or with controls. Any possible effect on IL-1 and TNF synthesis was not demonstrable, but production of these mediators had already been corrected by indomethacin treatment.

Although the results of immunologic screening demonstrated significant differences when regulation of acute phase response with immunomodulation was compared with controls, these differences had only a slight impact on the clinical outcome. The number of patients included in this study was obviously too small to demonstrate a significant clinical effect of immunomodulation. Further investigations with more patients will be necessary to achieve this. However, our study was able to demonstrate that immunomodulation can change alterations in the synthesis pattern of cytokines and mediators that are essential for the regulation of acute phase response.

The study was partially supported by grants DFG En 169/2-2.

We wish to express our thanks to Angela Kühn, Antje Uhlig, and Doris Stoll for skillful technical assistance.

Cardiac Preconditioning Does Not Require Myocardial Stunning

Max B. Mitchell, MD, Chris B. Winter, MD, Cristee R. Locke-Winter, BS, Anirban Banerjee, PhD, and Alden H. Harken, MD

Department of Surgery, University of Colorado Health Sciences Center, Denver, Colorado

Efforts to minimize the deleterious effects of intraoperative myocardial ischemia-reperfusion (I/R) injury have been primarily directed at optimizing cardioplegic solutions and altering reperfusion conditions. Classically, myocardial I/R has been associated with cardiac mechanical dysfunction ("stunning"). Recently, we reported an α_1 -adrenergic receptor-mediated mechanism of paradoxical myocardial protection against I/R insult induced by a prior episode of transient ischemia, a phenomenon known as "ischemic preconditioning." Myocardial stunning resulting from transient ischemia has previously been associated with ischemic preconditioning, prompting intuitively negative bias against the clinical application of this phenomenon. The purpose of this study was to determine whether transient ischemia of insufficient duration to cause prolonged mechanical dysfunction (stunning) can induce favorable cardiac preconditioning. Isolated-perfused rat hearts were allowed to equilibrate for 8 minutes and were then subjected to either 2 minutes of global, normothermic transient ischemia or 2 minutes

of 50 $\mu\text{mol/L}$ phenylephrine infusion. A stabilization period of perfusion lasting 10 minutes after the termination of transient ischemia or phenylephrine infusion was followed by a standard I/R challenge (20 minutes of global, normothermic ischemia; 40 minutes of reperfusion). Ventricular function (measured as developed pressure in millimeters of mercury) recovered rapidly after transient ischemia such that no impairment was present before the subsequent standard I/R challenge. Phenylephrine treatment was associated with no residual inotropy before I/R challenge. Control hearts were subjected only to the standard I/R challenge after an initial 20-minute equilibration period. After reperfusion control hearts exhibited 54.4% recovery of initial left ventricular developed pressure. Transient ischemia- and phenylephrine-preconditioned hearts recovered 84.4% ($p < 0.01$) and 82.4% ($p < 0.01$), respectively. We conclude that the benefits of myocardial preconditioning do not require the deleterious effects of myocardial stunning.

(*Ann Thorac Surg* 1993;55:395-400)

Efforts to reduce myocardial mechanical dysfunction after cardiac surgical procedures requiring cardioplegic arrest have been primarily directed at optimizing cardioplegic solutions [1] and, more recently, manipulating reperfusion conditions [2, 3]. Nevertheless, inotropic and mechanical support are still occasionally required to prevent morbidity and mortality from stunned myocardium [4]. Recent investigations have revealed the presence of intrinsic myocardial systems with exciting therapeutic implications that markedly enhance tolerance to myocardial ischemia/reperfusion (I/R) injury.

Murry and associates [5] have described paradoxical protection against prolonged ischemic insult afforded by a prior transient ischemic episode, a phenomenon known as "ischemic preconditioning." Classically, the preconditioning ischemic event has been associated with myocardial mechanical dysfunction ("stunning") persisting into the onset of the more extensive ischemic insult. We [6] have previously reviewed the associations between I/R, myocardial stunning, and cardiac preconditioning. Recent investigations [7] into the mechanism of ischemic precon-

ditioning have dissociated stunning as a causal factor; however, preconditioning has not previously been reported in the absence of stunning [8]. Induction of intrinsic protective mechanisms against I/R is clinically appealing. The intuitively negative bias, however, inherent to prophylactically stunning the heart before a cardiac operation limits the utility of this phenomenon. We have recently reported that ischemic preconditioning is mediated by α_1 -adrenoceptor stimulation via norepinephrine release induced by transient ischemia [9]. This study was undertaken (1) to determine whether acute cardiac preconditioning may occur in association with transient ischemia of sufficient brevity to allow rapid and complete functional recovery before a more extensive I/R insult and (2) to examine whether the α_1 -adrenoceptor-mediated mechanism of preconditioning can be exploited by exogenous pharmacologic agents, obviating the need for transient ischemia.

Material and Methods

Male Sprague-Dawley rats (325 to 350 g; Sasco Inc, Omaha, NE) were fed a standard diet and acclimated in a quiet quarantine room for 2 weeks before experimentation. The animal protocol was reviewed and approved by the Animal Care and Research Committee, University of

Accepted for publication May 14, 1992.

Fig 1. Schematic diagram of experimental protocol depicting representative courses of untreated and preconditioned hearts. All hearts were maintained a total of 80 minutes. Control hearts were perfused unperturbed for 80 minutes (a-f). Transient ischemia control hearts and phenylephrine control hearts were equilibrated 8 minutes (a) before 2-minute stimulation (b), then perfused unperturbed for 70 minutes (c-f). Untreated hearts were equilibrated 20 minutes (a-c) before the standard ischemia/reperfusion challenge (d-f). After corresponding preconditioning with transient ischemia (TI) or phenylephrine (α -1) hearts were stabilized 10 minutes (c) before standard ischemia/reperfusion challenge. (Phases: a = pretreatment equilibration [8 minutes]; b = preconditioning stimulation [2 minutes]; c = posttreatment stabilization [10 minutes]; d = ventricular failure at onset ischemia; e = continued ischemia [d + e = 20 minutes]; f = reperfusion [40 minutes].)

Colorado Health Sciences Center. All animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" (NIH publication No. 85-23, revised 1985). Unless otherwise noted all chemicals and reagents were obtained from Sigma Chemical Company, St. Louis, MO.

Preparation of Isolated Rat Heart

The isolated, crystalloid-perfused rat heart used in our laboratory has been previously described [10, 11]. Rats were anesthetized (sodium pentobarbital, 60 mg/kg, intraperitoneally) and heparinized (500 units, intraperitoneally). Hearts were rapidly excised, placed in iced oxygenated perfusate, mounted on a modified Langendorff apparatus, and perfused (70 mm Hg) with Krebs-Henseleit solution (1.2 mmol/L Ca^{2+} , 4.7 mmol/L KCl, 25.0 mmol/L NaHCO_3) in a retrograde fashion at the aortic root. A gas mixture (92.5% O_2 , 7.5% CO_2 ; S-070 oxygenator [Shiley Inc, Irvine, CA]) was used achieving a perfusate oxygen tension of 450 mm Hg, carbon dioxide tension of 40 mm Hg, and pH of 7.4. A water-filled latex balloon was inserted into the left ventricle through the left atrium and adjusted to a left ventricular end-diastolic pressure of 6 mm Hg. Pacing wires were fixed to the pulmonary outflow tract, and hearts were paced at 360 beats/min (pacer off during ischemia and drug infusions). Hearts that could not be paced at 360 beats/min were discarded. Ventricular developed pressure (DP) was continuously recorded with a direct pressure amplifier (Gould Electronics, Houston, TX). A three-way stopcock above the aortic root was turned to create global ischemia, during which the heart was placed in a degassed perfusate-filled organ bath maintained at 38°C.

Experimental Design

All experimental and control groups consisted of 5 animals. All hearts were kept on the perfusion apparatus for 80 minutes. A control group was perfused without interruption for the full 80 minutes to ensure stability of the

preparation. Experiments consisted of an equilibration period of 8 minutes and a subsequent preconditioning stimulus of 2 minutes, followed by a 10-minute period of perfusion (Fig 1). Hearts were then subjected to 20 minutes of global, normothermic ischemia and 40 minutes of reperfusion, our standard I/R challenge [10, 11]. Hearts that were not preconditioned (control I/R group) were allowed to equilibrate uninterrupted for 20 minutes followed by the standard I/R challenge.

Transient Ischemia

After the mandatory 8-minute equilibration period, pacing was discontinued and perfusion was interrupted for 2 minutes. Hearts (TI+I/R group) were placed in the 38°C organ bath during transient ischemia (TI). After the transient ischemic period, hearts were allowed to recover for 10 minutes (the poststimulus equilibration period), before subjecting them to the standard I/R challenge. A control group (TI control) was preconditioned but not subjected to the standard I/R challenge to assess for functional stability over the remainder of the protocol.

Pharmacologic Preconditioning

After 8 minutes of equilibration, phenylephrine (PE) dissolved in normal saline solution was infused for 2 minutes with a Harvard pump through a port above the aortic root such that a 50- $\mu\text{mol/L}$ solution was delivered into the coronary arteries. We have previously demonstrated preconditioning with this dose [9]. Hearts were not paced during drug infusion. After a 10-minute postinfusion stabilization period, this group (PE+I/R group) was subjected to the standard I/R challenge. A control group (PE control) was similarly treated with PE without the subsequent I/R challenge to assess for residual positive inotropy or deleterious drug effects.

Ventricular Failure in Ischemia

The time (in seconds) from the onset of the standard I/R challenge to complete ventricular failure in preconditioned

tioned heart (TI and PE) and untreated heart was measured from the continuous tracing of DP.

Statistical Analysis

Values for cardiac DP were compared by analysis of variance. Post hoc Scheffe's *F* test was applied to detect significant differences at a confidence level of *p* less than 0.01. Mean DP at the end of the initial 8-minute equilibration period in the standard I/R group was compared with the mean DP immediately preceding the standard I/R challenge. To assess for the presence of myocardial stunning or residual inotropy resulting from the preconditioning stimulus, identical comparisons were made in the TI and the PE groups, respectively. Recovery (expressed as percent recovery $\pm$ standard error of the mean) after the standard I/R challenge in the I/R, TI, and PE groups was calculated for individual hearts by dividing the DP at the end of reperfusion (see Fig 1, *f*) by the DP at the end of the initial 8-minute equilibration period (see Fig 1, *a*). Efficacy of preconditioning was evaluated by comparing the post-reperfusion recovery of the I/R group with the TI+I/R and PE+I/R groups, again using analysis of variance and applying post hoc Scheffe's *F* test with a confidence level of *p* less than 0.01. The mean times (seconds $\pm$ standard error of the mean) to complete ventricular failure at the onset of sustained ischemia for TI-treated, PE-treated, and untreated hearts were compared using analysis of variance and applying post hoc Scheffe's *F* test with a confidence level of *p* less than 0.05.

Results

The control group subjected to 80 minutes of continuous perfusion exhibited a loss of ventricular function of 8%. Figure 2 shows that a single 2-minute episode of transient normothermic ischemia (preceded by 8 minutes of equil-

Fig 2. Functional recovery with preconditioning: Left ventricular function after 80 minutes expressed as percent of initial left ventricular developed pressure (DP). Transient ischemia (TI) and 50 μ mol/L phenylephrine (PE) without the standard ischemia/reperfusion (I/R) challenge neither augment nor impair final function compared with control (CTRL). Hearts preconditioned with either TI or PE before standard I/R challenge (20 minutes of ischemia, 40 minutes of reperfusion) demonstrate improved functional recovery compared with unpreconditioned hearts.

Fig 3. Pretreatment function compared with posttreatment function before standard challenge: After transient ischemia (TI) there was complete return of function by the end of the stabilization period after preconditioning (see Fig 1, *c*). Hearts pretreated with phenylephrine (PE) before ischemia/reperfusion challenge (I/R) had a residual increase of 7.4 mm Hg ($p < 0.05$) at the corresponding time. Left ventricular developed pressure (DP) in hearts submitted to I/R alone was unchanged during the equilibration period (Fig 1, *a-c*). Thus, beneficial preconditioning does not require deleterious myocardial stunning.

ibration) and followed by 70 minutes of perfusion has no effect on ventricular function compared with control. Similarly, no deleterious effects were observed with a 50- μ mol/L PE infusion over 2 minutes. Additionally, no residual inotropic effect was observed in this group. The standard I/R challenge resulted in a postreperfusion recovery of $54.4\% \pm 3.3\%$ of initial ventricular function in untreated hearts. In contrast, preconditioning resulted in improved recoveries of $84.4\% \pm 1.0\%$ ($p < 0.01$) and $82.4\% \pm 3.2\%$ ($p < 0.01$) in the TI+I/R and PE+I/R groups, respectively, compared with standard I/R challenge alone.

Figure 3 demonstrates that no ventricular functional deficits (ie, stunning) persisted in the TI+I/R group before the onset of the standard I/R challenge. Rapid recovery of function occurred after the TI stimulus. The PE+I/R group exhibited no residual inotropy at the end of the postinfusion stabilization period. We conclude that myocardial dysfunction can completely recover after TI while myocardial preconditioning against a sustained ischemic insult is induced. Furthermore, equivalent cardiac preconditioning by exogenous α_1 -adrenoceptor stimulation can be achieved without any functional impairment. Finally, the time from the onset of the standard I/R challenge to complete ventricular failure was no different in untreated hearts compared with preconditioned hearts (I/R, 130 ± 4.5 seconds; TI+I/R, 131 ± 10.0 seconds; PE+I/R, 126 ± 10.1 seconds; $p > 0.05$). We conclude that a transient ischemic time insufficient to cause functional stunning, but sufficient to precondition, does not induce more rapid ventricular failure at the onset of sustained ischemia.

Comment

Myocardial stunning was originally defined mechanically as fully reversible prolonged ventricular dysfunction after

Fig 4. Hypothetical depiction of ventricular failure during ischemia: Theoretically, stunned heart should fail more rapidly than normal heart at the onset of ischemia. The area under each curve is theoretically proportional to energy expended during futile contractions early in ischemia. Reduced energy expenditure in stunned heart could result in net energy preservation (represented by the shaded area) during sustained ischemia contributing to preconditioning. We observed no difference in the failure rates of preconditioned and nonpreconditioned heart. Similarly, left ventricular developed pressure (DP) before the standard challenge were not different in these groups.

I/R insult of insufficient magnitude to cause cellular necrosis [4]. In both experimental models and clinical correlates of this phenomenon, contractile dysfunction persists an order of magnitude longer than the inciting ischemic event. Stunned heart is characterized by hypocontractility and reduced diastolic compliance that return to normal over a time span inversely related to the duration of the ischemic event. Intuitively, one might expect successive ischemic insults interposed by reperfusion to cause cumulative injury. Surprisingly, Murry and colleagues [5] demonstrated that a period of brief ischemia paradoxically renders myocardium resistant to the effects of subsequent ischemia, a phenomenon they termed "ischemic preconditioning." Their original canine model of ischemic preconditioning against subsequent prolonged I/R injury employed a transient ischemic time of 15 minutes, which by itself produced stunning lasting up to 3 days. These stunned hearts demonstrated markedly reduced infarct size after sustained ischemia compared with control. This observation led to the hypothesis that myocardial stunning may be causally associated with ischemic preconditioning [12, 13].

Murry and co-workers [13] have demonstrated that TI retards adenosine triphosphate depletion and slows both glycogenolysis and anaerobic glycolysis during a subsequent prolonged ischemic episode, yielding a net preservation of energy stores in preconditioned heart. At the onset of ischemia, ventricular contractions weaken rapidly (see Fig 1, *d*) with a transition to futile contractions followed by complete mechanical failure (see Fig 1, *e*). These investigators proposed that stunned myocardium subjected to a second episode of ischemia might exhibit more rapid mechanical failure with fewer futile contrac-

tions, therefore expending less energy during initial ischemia resulting in a net energy conservation in preconditioned heart (Fig 4) [7]. In our model we found no quantifiable difference in the rate of ventricular failure in preconditioned heart compared with untreated heart. Furthermore, if stunning is inexorably associated with preconditioning, the magnitudes of the two phenomena should be directly related, and the temporal course of each should coincide. That is, increased stunning might enhance preconditioning, and the preconditioning effect should persist concurrent with ventricular dysfunction. However, the severity of stunning has not correlated with favorable preconditioning. Miura and colleagues [14] demonstrated no correlation between the magnitude of stunning and the extent of resultant protection. Similarly, the duration of ischemic preconditioning does not correlate with the duration of mechanical dysfunction. Murry and associates [7] have noted marked attenuation of the protection afforded by ischemic preconditioning well before any recovery of mechanical function occurs. Miura and colleagues [15] likewise found that the protective effect of ischemic preconditioning lasted only 30 minutes, a time much less than that required for mechanical recovery from stunning in their model.

In this study we have demonstrated that ischemic preconditioning and myocardial stunning can be further dissociated. We observe that TI of sufficient brevity to allow complete mechanical functional recovery before the sustained ischemic insult effectively preconditions against the latter insult. Other investigators have shown that ventricular function of isolated rat heart returns within 90 seconds after a single 5-minute episode of global normothermic ischemia [16]. The time course for recovery after TI in our model was roughly equivalent to the duration of TI. This differs from classic models of stunning, in which recovery requires a time period much longer than the ischemic event. Furthermore, the time from the onset of ischemia to complete ventricular failure in preconditioned hearts (TI or PE) did not differ from control, suggesting that futile energy expenditure was similar in all groups.

The mechanism of myocardial stunning is unresolved; however, a leading hypothesis invokes toxic oxygen radicals elaborated upon reperfusion [6, 17]. This hypothesis is supported by numerous studies that demonstrate improved mechanical function achieved with free radical scavenger administration [18]. An early report suggested that free radical production at reperfusion may be a causative factor in preconditioning [12]. Administration of superoxide dismutase and catalase attenuated preconditioning in 50% of treated animals; however, the lack of an effect in the remaining animals could not be explained. A more recent investigation demonstrated no attenuation of ischemic preconditioning with superoxide dismutase and catalase administration [19]. Support for a mechanistic link between myocardial stunning and ischemic preconditioning is therefore lacking.

One could argue that a transient ischemic time of 2 minutes constitutes transient stunning. First, investigations of high-energy phosphate content in typical models of stunned heart have found adenosine triphosphate

reductions of 50% with slow repletion over a period of days [4]. However, other investigators have demonstrated that ischemia of 5 minutes' duration in isolated rat heart resulted in comparatively less adenosine triphosphate depression [16], and with reperfusion phosphocreatine overshoot coincided with the rapid return of ventricular function. Nevertheless, total adenosine triphosphate content remained depressed after recovery. Second, several investigators have shown that catecholamine stimulation can unmask contractile reserve in stunned heart [20-22]. We have previously demonstrated that endogenously released norepinephrine is increased after TI [9]; therefore, the rapid recovery after our 2-minute TI could reflect inotropic support from endogenous norepinephrine. However, endogenous catecholamine release is transient. Thus, catecholamine-dependent functional support should also be temporary, and a decline in mechanical function would be expected within the time frame of our model. The group that was allowed uninterrupted perfusion for 70 minutes after TI demonstrated no functional deterioration compared with control, indicating that the prompt return of ventricular contractility after TI is not catecholamine-dependent.

Recovery of myocardial function may precede metabolic recovery in stunned heart [17]. In the present study myocardial high-energy phosphate were not assessed. However, in an in vivo porcine model, other investigators have clearly demonstrated enhanced recovery of high-energy phosphate in heart preconditioned with transient ischemic durations sufficient to cause stunning [23]. Furthermore, in previous work we found that the improved functional recovery of preconditioned heart paralleled enhanced high-energy phosphate repletion during reperfusion [9]. Metabolic recovery was not different in hearts preconditioned with TI or norepinephrine. We believe that similar results would be found with PE.

Recently, we have determined that ischemic preconditioning is mediated by α_1 -adrenoceptor stimulation caused by norepinephrine release from myocardial sympathetic neurons [9]. Endogenous catecholamine release in response to ischemia as observed in our model should also occur with transient ischemic durations sufficient to cause significant stunning. Clearly, preconditioning by pharmacologic means does not require ventricular dysfunction. Conceivably, exogenous α_1 -adrenoceptor stimulation could be analogous to stunning. However, other investigators have recently attributed ischemic preconditioning to the activation of adenosine A_1 receptors by adenosine released during TI [24]. The α_1 and adenosine A_1 mechanisms may be interrelated [6].

This study demonstrates that the benefits of cardiac preconditioning do not require the deleterious effects of myocardial stunning in isolated rat heart. Subsequent in vivo validation of these findings would encourage the clinical application of preconditioning. The ability to simulate ischemic preconditioning by pharmacologic manipulation of myocardial receptors, without incurring antecedent functional impairment, has significant clinical implications. The scheduled nature of I/R stress sustained during cardiac operations should allow for the prophylac-

tic exploitation of pharmacologically induced preconditioning. The healthy myocardium of donor heart makes heart transplantation an ideal setting for the therapeutic application of this phenomenon. Further investigation of the signaling events and intracellular effectors of preconditioning may yield even more suitable applications for clinical cardiac preconditioning.

Supported by grant HL43696 from the National Institutes of Health.

INVITED COMMENTARY

Heart muscle differs from other tissues of the mammalian organism because of its high energy requirements to support contraction. Because its energy needs far exceed its adenosine triphosphate stores (human heart utilizes about 35 kg of adenosine triphosphate per day, whereas its adenosine triphosphate stores amount to not more than 300 mg, ie, a 100,000-fold difference!), the heart relies on the continuous supply of oxygen and substrates to fuel oxidative phosphorylation. The intricate network of metabolic control through intermediary metabolism of substrates provides a responsive system to the energy needs of the heart. Under normal conditions there is tight, beat-to-beat coupling between substrate utilization, oxygen consumption, and cardiac work. Consequently, ischemia results in an almost instantaneous decline in contractile function.

Protection of the ischemic and reperfused myocardium is a prerequisite for successful cardiac operation and transplantation. For the most part this protection is afforded by cardioplegic solutions, often in combination with hypothermia. Conventional methods reach their limits in patients with compromised contractile function before operation, in patients requiring prolonged periods of ischemic arrest, and in situations calling for prolonged ex vivo storage of donor hearts for cardiac transplantation. Investigators have therefore recently turned to new mechanical, pharmacological, or metabolic measures to protect the jeopardized myocardium. Of these methods, ischemic preconditioning (a term used to describe enhanced tolerance to prolonged periods of ischemia after

one or more brief periods of ischemia followed by reperfusion) has received most of the attention.

Although the mechanism of ischemic preconditioning is not clear, several important aspects of the phenomenon are now coming to light. The present study by the Denver group concludes that, although ischemic preconditioning is not associated with stunning, it can nevertheless be mimicked by α -adrenergic stimulation. This is an intriguing concept. However, critics may argue that "pharmacological preconditioning" has not brought us any closer to understanding the mechanism of the phenomenon. A positive study in rat hearts is not sufficient reason to test the same hypothesis in patients, and more work is clearly needed. The results should furthermore be considered in the wider context of other preischemic manipulations found to enhance ischemia tolerance such as increasing myocardial glycogen ("glycogen loading") or raising the levels of free radical scavengers.

We begin to see that there are many facets to preconditioning. As investigators turn their attention to the myocardium itself, we can hope that a unified, clinically useful concept on preconditioning may soon emerge. The present study is a step in the right direction.

Hyperbaric Oxygenation for Arterial Air Embolism During Cardiopulmonary Bypass

Shahar Kol, MD, Ron Ammar, MD, Giora Weisz, MD, and Yehuda Melamed, MD

Israeli Naval Hyperbaric Institute and Department of Cardiovascular Surgery, Carmel Lady Davis Hospital, Haifa, Israel

The incidence of systemic air embolism during cardiopulmonary bypass is estimated to be 0.1%. However, the vast majority of instances are unreported and quietly ignored. The result may be disability or death. The control of air embolism obviously lies in prevention. The definite and specific treatment of this complication is hyperbaric oxygen. We report 6 patients referred to our institute because of air embolism during cardiopulmonary bypass. Of the 4 patients in whom hyperbaric oxygen therapy was delayed for 17 to 20 hours, 2 showed

partial neurological improvement, as opposed to the success of hyperbaric oxygen therapy in the 2 patients in whom the delay was minimal. We conclude that as soon as the proposed open heart operation has been completed and there is an indication that air embolism has occurred, the patient should be treated with hyperbaric oxygen as quickly as possible, even before neurologic manifestations of cerebral ischemia appear.

(*Ann Thorac Surg* 1993;55:401-3)

Arterial air embolism during cardiopulmonary bypass can result in serious brain damage or fatality. The incidence of this complication is estimated to be 0.1% [1, 2]. Currently more than 3,500 operations with cardiopulmonary bypass are performed annually in Israel, so that 3 patients with air embolism may be expected. Despite improvements in equipment and technology, these accidents still occur, demanding quick and accurate diagnosis and efficient therapeutic measures.

The immediate management includes Trendelenburg position, hypothermia, steroids, anticoagulants, oxygen, and volume expansion [3, 4]. Retrograde perfusion has been suggested as a means of decreasing the amount of air obstructing the cerebral circulation [5, 6], yet only 47% of the gas was recovered by this modality in an animal model [4]. The definite and specific treatment of this complication is hyperbaric oxygen (HBO). It has been concluded that every heart surgeon should ascertain the nearest hyperbaric facility and should adopt a contingency plan to be followed in the event of air embolism [7, 8].

We report 6 patients referred to our institute since January 1985 because of arterial air embolism during cardiopulmonary bypass. In each case diagnosis was made by the referring surgeon, based on his suspicion that a considerable amount of air had entered the systemic circulation during the operation. The patients were treated in a large multiplace hyperbaric chamber. The chamber is the only hyperbaric referral facility in Israel, and so these 6 patients reflect the total national clinical experience.

Case Summaries

Six patients were referred with a diagnosis of air embolism. Of the 4 patients who had undergone coronary artery bypass grafting, 2 had undergone additional surgical procedures. The fifth patient had undergone closure of an atrial septal defect, whereas aortic valve replacement had been carried out in the sixth.

Two of the patients were referred immediately on completion of the operation, which made it possible to commence HBO therapy with a delay of only 2 to 3 hours. These 2 patients made a complete recovery. In the remaining 4 cases, the surgeons preferred to wait and observe the impact of the embolism on the recovery process. Only when normal recovery was not observed the following day were these patients referred for HBO. This resulted in a considerable delay in the commencement of therapy. Two of the 4 patients died, 1 was left with severe neurological impairment, and 1 was left with a mild motor deficit in one leg. In 5 cases, a modified version of the US Navy treatment table 6A was used (Fig 1). One patient was given 90 minutes of oxygen at 2.8 atmospheres absolute. The main clinical data are summarized in Table 1.

Comment

Arterial air embolism accompanying cardiopulmonary bypass may result in disability or even death. In a survey of 349 cardiac surgeons [1], the incidence of arterial air embolism was estimated to be 0.1%, but its true incidence seems to be higher [7]. The vast majority of instances are unreported and quietly ignored, mainly due to a fear of litigation.

According to the statistics of Stoney and associates [1], there were 429 instances of arterial air embolism in 374,819 cardiopulmonary bypass operations (0.11%). Of these, 61 resulted in disability (14.2%), and 92 patients

Fig 1. US Navy Treatment Table 6A. This graph indicates the pressure (depth in feet) inside the hyperbaric chamber at any given time, the rate at which pressure is increased or reduced, and the gas breathed during the various stages of the treatment. Solid areas denote intervals of exposure to pure oxygen, and open areas intervals of exposure to air. The table is used by us in a modified form. To increase the oxygen partial pressure during the first 30 minutes of therapy, a 50%/50% nitrogen/oxygen mixture is introduced instead of air at this critical stage.

(21.4%) died of the complication, which can occur at the onset of perfusion, during perfusion, or on resumption of cardiac function [7].

A number of causes of air entry into the bypass circuit have been documented, including rupture of arterial lines and connectors, oxygenator defects, arterial reservoir run dry due to insufficient venous return, and sudden acceleration of a roller pump [9, 10].

The control of air embolism lies in prevention. It is incumbent upon each open heart team to be prepared to deal with the situation should it arise. Guidelines for this and other emergency procedures should be established and practiced by the perfusionist team. The management of gross air embolism should include the following [11]:

1. The arterial pump is immediately stopped and the venous line clamped.
2. The patient is placed in a steep head-down position.

3. The aortic cannula is removed and the arterial circuit purged of air.
4. The arterial cannula is connected to the venous line to facilitate retrograde perfusion. Alternatively, the atrium can be cannulated separately.
5. Retrograde perfusion at a flow of 1 to 2 L/min and at a temperature of 20°C is carried out with the flow directed up the superior vena cava. This is continued for a few minutes with the suction system being used to retrieve blood exiting from the aortotomy.
6. The anesthetist exerts pressure on the carotid arteries, and retrograde perfusion is continued until the arterial system is cleared of air. In extreme cases, retrograde perfusion through the inferior vena cava may also be required.
7. Standard bypass is resumed with hypothermia, and attention is turned toward removing any air that may have entered the coronary system, by pharmacological

Table 1. Main Clinical Data

Patient No.	Age (y)	Sex	Operation	HBO Therapy	Time to HBO (h)	Main Symptoms	Outcome
1	53	M	CABG	6A ^a	17	Coma; mechanically ventilated; no response to pain; hypotonia	No response; severe impairment
2	62	F	CABG + carotid endarterectomy	2.8 ATA, 90 min	18	Coma; mechanically ventilated; hypotonia	No response; died
3	57	M	CABG + mitral valve replacement	6A ^a	20	Coma; mechanically ventilated; responsive to pain	Improved
4	4	F	Closure of ASD	6A ^a	2	Coma; mechanically ventilated	Complete recovery
5	55	M	CABG	6A ^a	20	Coma; mechanically ventilated; no response to pain; pupils dilated	No response; died
6	70	F	Aortic valve replacement	6A ^a	3	Coma; mechanically ventilated; pupils reactive to light	Complete recovery

^a Modified

ASD = atrial septal defect; ATA = atmospheres absolute; CABG = coronary artery bypass grafting; F = female; HBO = hyperbaric oxygen; M = male.

elevation of the perfusion pressure and small-needle puncture of the distal coronary system.

8. The operative cardiac procedure is completed as quickly as possible.

Rewarming is carried out slowly to a core temperature of 35°C, and bypass is completed in the usual fashion. The patient is ventilated on 100% oxygen. The value of steroid therapy is unproven, but it may be beneficial. Hyperosmolar and diuretic therapy is mandatory and ideally should be monitored with intracranial pressure.

Hyperbaric oxygen is considered a specific therapy for air embolism because it is based on the mechanical compression of air bubbles according to Boyle's law: the volume of a gas is inversely proportional to the pressure to which it is exposed [8, 12]. Hence compression to 6 atmospheres absolute will reduce the size of an intravascular bubble to one sixth of its original volume, which is 55% of its original diameter. This reduction helps relieve the vascular obstruction and restores perfusion. Concomitantly, HBO reduces the blood nitrogen partial pressure, increases the gradient between the bubbles and the blood, and accelerates bubble resorption. In addition, HBO both increases ischemic brain tissue oxygenation and reduces brain edema by vasoconstriction [7].

Winter and colleagues [13] and Tomatis and co-workers [8] indicated that HBO therapy may be lifesaving even after a delay as great as 11 hours, before irreversible brain damage. Mader and Hulet [14] predicted that HBO therapy may be useful in the treatment of cerebral air embolism even if this therapy is delayed more than 24 hours after embolization. This is in accord with our experience [15].

Because minor air embolism is so common and the immediate clinical impact seems, erroneously [16], to be negligible, the cardiac surgeon is reluctant to refer the patient for HBO therapy, even when a major air embolus is seen entering the arterial circulation. Only when the patient remains comatose some hours later is HBO therapy considered.

Because our chamber is the only hyperbaric referral facility in Israel, our experience represents the total number of patients referred for HBO therapy since 1985. According to statistics from the Israel Ministry of Health, in the course of these 6 years 16,332 operations with cardiopulmonary bypass were performed. According to Stoney and associates [1] the estimated number of patients with air embolism during this time would be 16. We believe, then, that the 6 patients described reflect only a fraction of the patients who should have been referred for HBO. It might be mentioned that ground transportation using a mobile intensive care unit proved safe in all 6 cases, and caused no further morbidity. The multiplace chambers in most hyperbaric centers can offer continuous intensive care during HBO therapy, as mechanical ventilators and monitoring equipment are available.

Definite conclusions cannot be drawn from the 6 patients described, but of the 4 patients in whom HBO therapy was delayed for 17 to 20 hours, only 1 showed significant neurologic improvement (patient 3), as opposed to the success of HBO therapy in patients 4 and 6, in whom the delay was minimal.

We conclude that massive arterial air embolism should be treated with HBO as quickly as possible, even before neurologic manifestations of cerebral ischemia appear.

Noninvasive Hemodynamic Assessment of the Internal Mammary Artery in Myocardial Revascularization

Jacques A. M. van Son, MD, PhD, Stefan H. Skotnicki, MD, Michiel B. M. Peters, MD, Nico H. J. Pijls, MD, PhD, Luc Noyez, MD, and Wim N. J. C. van Asten, PhD

Clinical Vascular Laboratory, Department of Thoracic and Cardiac Surgery, and Department of Cardiology, University Hospital Nijmegen St. Radboud, Nijmegen, the Netherlands

Using transthoracic B-mode imaging and Doppler spectrum analysis it was found that the luminal diameter of the internal mammary artery and its hemodynamics were not significantly different among 15 preoperative patients (64 ± 10 years) who underwent myocardial revascularization using the left internal mammary artery and young and older control groups (25 ± 3 years and 61 ± 9 years, respectively). These data indicate that older age does not significantly adversely influence the degree of intimal thickening and compliance in the internal mammary artery. Doppler spectrum analysis of the internal mammary artery in the patients who were operated on revealed conversion from a triphasic systolic waveform preoperatively to a unidirectional combined systolic/

diastolic waveform at 1 week and 2 and 6 months postoperatively, characterized by a significant increase in the diastolic blood flow velocity and a significant decrease in the systolic blood flow velocity and the pulsatility and resistance indices. This study indicates that transthoracic B-mode imaging and Doppler spectrum analysis are promising noninvasive techniques in the preoperative assessment of internal mammary artery morphology and physiology. In addition, Doppler spectrum analysis can also be used in the long-term serial assessment of the internal mammary artery conduit after myocardial revascularization.

(*Ann Thorac Surg* 1993;55:404-9)

During the last decade there has been a steep increase in the rate of myocardial revascularization procedures using the internal mammary artery (IMA). Preoperative angiographic and intraoperative ultrasonic imaging of the coronary arteries, as performed in some centers, provides primarily morphologic information about the IMA [1-4]. Intraoperative Doppler spectrum analysis of blood flow velocities in coronary artery bypass grafts and coronary arteries may provide valuable information with regard to intraoperative graft function and coronary blood flow characteristics, but fails to provide insight in the preoperative and postoperative hemodynamics of the IMA [5-10]. Such data may be important with regard to preoperative assessment of suitability of the IMA as a coronary artery bypass graft and postoperative assessment of graft function. In our search for a reliable noninvasive diagnostic technique for preoperative and postoperative hemodynamic assessment of the IMA in myocardial revascularization we used an echo-Doppler apparatus in which a B-mode real-time two-dimensional imaging system is combined with a pulsed Doppler unit.

The objectives of this study were (1) investigation of the clinical applicability of transthoracic B-mode ultrasonic imaging and Doppler spectrum analysis in the preoperative and postoperative morphologic and functional assess-

ment of the IMA as a conduit in myocardial revascularization and (2) investigation of the anticipated postoperative change in hemodynamic pattern in the IMA.

Material and Methods

The study group, which has been described previously [11], consisted of 15 patients, between 45 and 80 years of age (mean age, 64 ± 10 years), who all underwent elective myocardial revascularization using the left IMA and additional reversed saphenous vein aortocoronary grafts. Postoperatively, none of the patients was on vasoactive medication. The postoperative hematocrit ranged from 0.35 to 0.41.

Transthoracic B-mode images and Doppler spectra were obtained (or an attempt was made to obtain them) from all left IMAs (that were all used as bypass conduits) and from all right (nonused) IMAs. Both techniques were applied preoperatively, at the end of the first postoperative week; and at 2 and 6 months postoperatively. After informed consent was obtained, postoperative angiograms of the IMA conduit were made in 5 patients as a morphologic reference for the postoperative ultrasonic assessment of graft function.

Similar to the patient group, in two control groups transthoracic B-mode imaging and Doppler spectrum analysis were applied to investigate both IMAs. The first control group consisted of 20 young, healthy volunteers,

Accepted for publication May 15, 1992.

Address reprint requests to Dr van Son, Division of Thoracic and Cardiovascular Surgery, Mayo Clinic, Rochester, MN 55905.

with ages ranging from 22 to 30 years (mean, 25 ± 3 years). The second control group consisted of 20 age-matched (range, 45 to 76 years; mean, 61 ± 9 years) and sex-matched patients who had been admitted for noncardiac diseases and who were subjected to the same noninvasive measurements.

For all echo-Doppler examinations the scanner head was positioned at the first intercostal space with the patient in the supine position. Guided by the B-mode image, the Doppler sample volume was placed in the IMA in such a way that the ultrasound beam had an angle of 60 ± 7 degrees to the axis of blood flow. An echo-Doppler apparatus (Toshiba SSA 270A duplex scanner, Tokyo, Japan) with a 5-MHz linear array transducer was used for the color B-mode imaging and for the recording of the Doppler spectra. In all patients, both preoperatively and postoperatively, the cross-sectional diameter of the IMA was measured (or we attempted to measure it) with B-mode imaging. Subsequently, Doppler signals from the IMA were recorded. Our technique of Doppler spectrum analysis has been described previously [11-13]. Three parameters were calculated to describe the shape of the Doppler spectrum curves, namely, the maximum frequency, the end-diastolic frequency, and the mean frequency [14]. The pulsatility and resistance indices, which both are dimensionless figures, were derived by combining different parameters [11, 15-18].

All IMA harvesting and intraoperative measurements were performed by an observer who was not aware of the results of the preoperatively measured IMA diameter. The IMA was mobilized with its pedicle from the first or second rib to a point 1 to 3 cm distal to the bifurcation into the superior epigastric and musculophrenic branches and subsequently divided distally. Low-current electrocoagulation was used for harvesting, and Hemoclips (Edward Weck and Co, Research Triangle Park, NC) were applied to large branches. The external IMA diameter was measured as proximal as possible (at the first or second intercostal space) by use of a sterile caliper and was correlated with the preoperatively measured luminal IMA diameter.

Values are expressed as mean values $\pm$ standard deviation. The differences between two means were compared by paired and unpaired Student's *t* tests. The criterion for statistical significance was a *p* value of 0.05 or less.

Results

Suitable B-mode images of the IMA could be obtained in all 15 preoperative patients and in all control individuals (Fig 1). Postoperatively this was achieved in all nonused IMAs and in 7 of 15 IMA conduits (47%). Therefore, the postoperatively measured luminal diameters of the IMA conduits were not used for further analysis. In addition to measurements of the luminal IMA diameter, it was possible to identify wall thickening and vessel calcification, although such phenomena were observed in only 2 patients and in none of the control individuals. There were no significant differences in the luminal IMA diameter among the three groups (Table 1). In the patient group the

Fig 1. Preoperative B-mode image of internal mammary artery (large arrow) at level of the first intercostal space. There is no sign of local intimal thickening. The luminal diameter at the site of the red mark (between small arrows) is 3.6 mm. The blue mark indicates the internal mammary vein.

preoperatively noninvasively measured luminal IMA diameter (3.3 ± 0.3 mm) correlated well with the intraoperatively measured external diameter (4.2 ± 0.5 mm), considering the fact that the width of the IMA wall is approximately 300 to 400 μ m [19].

Adequate Doppler spectra of the IMA could be obtained in all preoperative patients and control individuals. Postoperatively adequate Doppler spectra were obtained in all nonused IMAs and in 14 of 15 IMA conduits (93%). Figure 2 shows typical examples of the blood flow velocity waveforms as observed in the control groups and the preoperative patients. In all individuals a triphasic waveform was obtained with a large systolic peak followed by small reversed and diastolic flow components. There were

Table 1. Doppler Spectrum Parameters and Luminal Diameter as Measured in Both IMAs in Young Control Group (A) and Control Group of Similar Age as Patient Group (B), and in Right IMA in the Preoperative Patient Group^a

Parameter	Control (A)	Control (B)	Patients
No. of IMAs	40	40	15
Mean age (y)	25 ± 3	61 ± 9	64 ± 10
F _{max} (Hz)	$2,026 \pm 250$	$1,809 \pm 317$	$1,984 \pm 402$
F _{dia} (Hz)	209 ± 75	155 ± 118	135 ± 106
Adv (Hz)	503 ± 97	528 ± 146	469 ± 107
RI	0.90 ± 0.04	0.91 ± 0.07	0.93 ± 0.06
PI	3.9 ± 1.4	4.0 ± 1.6	4.4 ± 1.5
Preop diameter (mm)	3.2 ± 0.4	2.9 ± 0.6	3.3 ± 0.3

^a Values are shown as mean $\pm$ standard deviation.

Adv = mean frequency of curve; F_{dia} = end-diastolic frequency of advancing curve; F_{max} = maximum frequency of advancing curve; IMA = internal mammary artery; PI = pulsatility index; RI = resistance index.

Fig 2. Typical Doppler spectra as obtained from the internal mammary artery in (A) control individual of similar age as patients who underwent myocardial revascularization with internal mammary artery and (B) patient who underwent myocardial revascularization with internal mammary artery (preoperative situation). Mark at top indicates beginning of systole.

no significant differences in the five Doppler spectrum parameters among the three groups (Table 1).

Postoperatively 12 patients were in New York Heart Association functional class I, and 3 patients were in class II. In all 14 patients in whom adequate postoperative Doppler spectra of the IMA conduit were obtained the preoperative triphasic waveform had been converted into a combined systolic/diastolic waveform. In 12 patients an early systolic peak was followed by a lower diastolic peak (Fig 3), whereas in 2 patients a different waveform was observed, consisting of an early systolic peak followed by abrupt approximation of the blood flow velocity to zero and a large diastolic component that exceeded the systolic component (Fig 4). In all 14 patients the postoperative hemodynamics were characterized by a significant increase in the end-diastolic and mean frequencies and a significant decrease in the maximum frequency and the pulsatility and resistance indices (Table 2). These changes were maximal at 2 months postoperatively and then gradually declined, but remained significant at 6 months postoperatively. Postoperative angiography in 5 patients showed normal IMA conduits and widely patent IMA-coronary artery anastomoses, with proximal IMA side branches at the level of the first intercostal space appearing in two of the five angiograms (Fig 5). The hemodynamic data as obtained from the nonused IMA have been reported previously [11].

Comment

In the IMAs of all preoperative patients and all control individuals we documented a triphasic Doppler waveform with a high blood flow velocity during systole followed by a much smaller or absent diastolic component. There was a considerable physiologic spread in IMA blood flow velocity among the various individuals. This spread is caused only to a minimal extent by dependency on the insonation angle, because it was maintained rather constant in all measurements. We did not correct for the slight variations in insonation angle because their signif-

IMA luminal diameter among both control groups and the preoperative patients. Thus older age did not adversely influence the compliance and the degree of intimal thickening in the IMA. This finding may reflect the fact that the presence of a relatively large number of elastic lamellae in the media of the IMA, combined with a well-formed internal elastic lamina, even at advanced age, protects

against intimal thickening and, secondarily, atherosclerosis of this vessel [19-21].

In all IMAs that were used as a conduit for myocardial revascularization we observed conversion from a triphasic blood flow velocity waveform preoperatively to a unidirectional waveform postoperatively. This profound change in waveform pattern remained rather constant during the first 2 postoperative months and then declined, but remained significant at 6 months postoperatively in comparison with the preoperative situation. The unidirectional waveform pattern is considered to be caused by the low resistance of the coronary arterial bed, resulting in a marked increase of diastolic flow through the IMA conduit. In addition, in analogy to the postoperatively observed temporary increase in diastolic flow in the nonused IMA [11], the diastolic flow in the IMA conduit is temporarily enhanced in the early postoperative stage as a result of reactive hyperemia.

In this study we have demonstrated the clinical applicability of Doppler spectrum analysis in the preoperative assessment of suitability of the IMA as a bypass graft in myocardial revascularization and the potential utility of this technique in the postoperative functional assessment of the IMA conduit. The superficial location of the IMA and its relative freedom from severe atherosclerosis contribute to the fact that the results of echo-Doppler scanning of the IMA are generally excellent. In addition, our study shows that B-mode imaging allows accurate preoperative assessment of the luminal IMA diameter, although this may be limited in case of vessel calcification [22, 23]. Another study has demonstrated that B-mode imaging may identify normal and atherosclerotically diseased vessels as verified by contrast angiography [24]. Accurate postoperative measurement of the luminal IMA diameter with B-mode imaging, however, was possible in only 47% of the patients in this study. This low success rate may be primarily due to the fact that successful postoperative B-mode imaging of the IMA is highly dependent on the postoperative course of the vessel and as such is generally jeopardized if the IMA has been dissected free from the chest wall at the first intercostal space.

Preoperative assessment of suitability of the IMA as a conduit in myocardial revascularization may especially be

Fig 5. Postoperative angiogram of left internal mammary artery anastomosed in a sequential fashion to two marginal branches and the circumflex branch of the left coronary artery. Note side branches at the level of the first intercostal space.

valuable in patients who previously have been subjected to median sternotomy or mediastinal irradiation and in those with generalized atherosclerotic disease, such as may be the case in diabetics [25]. Currently, we almost routinely combine use of Doppler spectrum analysis and B-mode imaging in the preoperative and postoperative hemodynamic assessment of the IMA. Such a study can be performed in 20 to 30 minutes with a learning curve of only 2 to 3 weeks. The interobserver variability of this technique is small as long as the insonation angle is kept constant (60 degrees).

Quantitative velocity waveform analysis provides important physiologic data of bypass graft hemodynamics that are not available in pressure or volume flow measurements. The configuration and magnitude of the graft velocity waveform are a function of driving pressure, wall compliance, luminal diameter, and outflow resistance of the coronary arterial bed and of any side branches of the in situ arterial graft [8]. From other studies that applied intraoperative Doppler spectrum analysis in myocardial revascularization procedures, it is known that the graft flow pattern varies with the type and number of outflow coronary arteries [7, 8]. In grafts to the left coronary artery the blood flow velocity is highest in mid-diastole with flow approximating zero in early systole, followed by antegrade flow at end-systole [8, 10, 26, 27]. Grafts to the right coronary artery, however, show forward flow throughout the pulse cycle reflecting the lower right ventricular compressive forces during systole [26]. Recognition of normal systolic and diastolic flow patterns in bypass grafts, in the absence of technical error, may be used to evaluate the effects of revascularization on myocardial contractility. Abnormal flow patterns, such as predominantly systolic flow in a bypass graft to the left ventricle, may indicate diminished local left ventricular contractility [26].

Analogous to intraoperative Doppler spectrum analysis of the IMA conduit, postoperative application of this technique may also detect abnormal flow patterns. Postoperative Doppler spectrum analysis has the ability to detect poor IMA graft function, as evidenced by low to absent diastolic flow velocity, as other investigators have demonstrated intraoperatively [8] and as we have observed postoperatively in serial studies in a few patients who were not incorporated in this study. Such ultrasonic findings may warrant subsequent performance of IMA angiography to detect potential anatomic causes of poor graft function. A number of factors, however, may limit the usefulness of postoperative Doppler spectrum analysis as performed in this study. First, because all postoperative Doppler spectra in this study were obtained from the proximal segment of the IMA, the recorded spectra show a predominantly systolic waveform. In contrast, intraoperative Doppler spectrum analysis of the IMA at the mid or distal conduit level, as performed by us [10], showed a predominantly diastolic pattern. Therefore, in applying postoperative Doppler spectrum analysis as done in this study, any abnormal myocardial contractility, indicative of myocardial damage, may be incorporated in the predominantly systolic waveform. Second, flow sig-

nals resulting from flow distal to residual IMA branches may obscure recognition of flow disturbances resulting from more distal IMA or coronary pathology. Third, the expression of the systolic component as encountered in the proximal IMA conduit may vary with the length of the IMA conduit between the measuring site and the IMA-coronary artery anastomosis.

In summary, preoperative transthoracic B-mode imaging and Doppler spectrum analysis of the IMA are promising techniques in the preoperative morphologic and functional assessment of this vessel. Doppler spectrum analysis may also be used in the postoperative serial assessment of IMA graft function. Postoperatively, in the normally functioning IMA conduit, a lasting significant increase in the diastolic blood flow velocity and decrease in the systolic blood flow velocity are observed, secondary to anastomosis of the IMA to the low-resistance coronary arterial bed.

Role of Autogenous Tissue Factors in Hemolysis During Cardiopulmonary Bypass Operations

Edward G. Ford, MD, Anthony L. Picone, MD, and Clinton E. Baisden, MD

Department of Surgery, Keesler Medical Center, Keesler Air Force Base, Mississippi

Pericardial fluid has been implicated as a causative factor in hemolysis during cardiopulmonary bypass operations. Preoperative blood samples were obtained from 10 patients undergoing coronary artery bypass grafting for ischemic myocardial disease. Whole blood samples were separately incubated with autogenous pericardial fluid, pericardium, pleura, vein, skeletal muscle, and fat harvested during the operative intervention. The plasma fraction was separated by centrifugation and assayed for serum free hemoglobin. Statistical analysis was accomplished by the Bonferroni technique to adjust for multiple comparisons. Pericardial fluid-induced hemolysis

was least (20.7 mg/dL). Pleura and muscle contributed significantly to the serum free hemoglobin level (56.3 and 112.3 mg/dL, respectively; $p < 0.05$). Pericardium, vein, and fat did not cause significant elevations of the serum free hemoglobin level. Postbypass hemolysis is an important management consideration that may be minimized by delicate tissue manipulation and attention to minimizing tissue trauma. Avoidance of aspiration of pericardial fluid into the autotransfusion system is not supported.

(*Ann Thorac Surg* 1993;55:410-2)

Blood transfusion requirements during cardiovascular surgical interventions have decreased with use of blood scavenging apparatus and autotransfusion [1, 2]. Hemolysis after cardiopulmonary bypass-supported operations has been variously attributed to direct mechanical trauma from the scavenging apparatus or the bypass circuit. An early report by Morris and associates [3] suggested that mechanical trauma to the red blood cell may play a minor role in hemolysis and, instead, that the major determinant of corpuscle destruction was contact with pericardial and pleural surfaces. This study is quoted as a rationale, in some institutions, for avoiding aspiration of pericardial or pleural fluid collections into the cell scavenging apparatus used during cardiopulmonary bypass operations. We present our experience and review the tendency of various solid and fluid tissues to cause destruction of red corpuscle membranes, as evidenced by liberation of serum free hemoglobin.

Material and Methods

Adult patients scheduled for elective coronary artery bypass grafting in management of myocardial ischemic disease were studied. After anesthetic induction, 15 mL of arterial blood was drawn from each patient and placed in standard hematological tubes containing EDTA. Pericardial fluid was sampled by aspiration immediately before the pericardium was opened to minimize blood contamination of the fluid. Pericardium, pleura, and subcutaneous fat were harvested before bypass grafting. Skeletal

muscle was harvested from the distal portion of the mammary artery pedicle. Vein was harvested with saphenous vein grafts from the lower leg. One-half gram samples of each tissue type (solid and fluid) were separately incubated in the tubes containing EDTA and whole blood at 37°C for 30 minutes with gentle agitation. Whole blood in EDTA served as the study control. Whole blood hemolyzed in a 1:1 mixture with distilled water served as the indicator of maximal expected hemolysis. After incubation, samples were centrifuged at 2,500 rpm for 15 minutes on an Eppendorff No 5415 centrifuge, and the supernatant was decanted. The supernatant was assayed for serum free hemoglobin on a Perkin Elmer Lambda 4C UV/VIS ultraviolet spectrophotometer at 380 nm, 415 nm, and 450 nm. Serum free hemoglobin content in milligrams per deciliter was calculated as $83.6 [(2 \times A_{415 \text{ nm}}) - A_{380 \text{ nm}} - A_{450 \text{ nm}}]$, where 83.6 = constant of absorption of 1 L of oxyhemoglobin and A = absorbance [4].

Informed consent was obtained from all subjects before study. The study protocol, informed consent, and tissue processing were accomplished in strict accordance with, and the approval of (Jan 1991), guidelines established by the Institutional Review Committee and Department of Defense regulations. Statistical comparisons were accomplished with Bonferroni's technique to adjust for multiple comparisons.

Results

Ten patients (7 male, 3 female) aged 52 to 70 years (mean, 62 years) undergoing elective coronary artery bypass grafting were studied. The operative approach was through a median sternotomy, and grafting was accomplished with mammary artery and saphenous vein grafts. All interventions were uncomplicated.

Table 1. Serum Free Hemoglobin Concentrations by Site

Site	Mean (mg/dL)	Standard Deviation (mg/dL)	Median (mg/dL)	Range (mg/dL)	Comparison With Plasma Control ^a
Muscle	112.3	174.3	48.5	12.5-586.8	$p < 0.05$
Pericardium	39.6	42.1	26.3	5.9-148.0	NS
Pericardial fluid	20.7	35.8	9.2	4.2-121.2	NS
Pleura	56.3	62.8	25.1	10.9-174.7	$p < 0.05$
Vein	28.0	17.0	26.4	8.4-61.9	NS
Fat	35.8	16.0	31.4	15.9-71.9	NS
Hemolyzed RBC	5,076	1,728	5,213	2,316-8,912	$p < 0.05$
Plasma control	15.1	16.0	9.9	2.5-54.3	NS

^a Comparison of median concentration at each site with plasma control group, using the Bonferroni method of adjusting for comparisons.

NS = not significant; RBC = red blood cells.

Hemolysis was demonstrated with each of the tissues studied. Hemolysis with pericardium, pericardial fluid, vein, and fat was not statistically significantly different than controls (Tables 1, 2). Pleura ($p < 0.05$) and skeletal muscle ($p < 0.05$) incubations demonstrated statistically significant elevations in serum free hemoglobin. Table 1 provides a summary of hemoglobin concentrations for each group and a comparison of the median concentration with that of the control group. Table 2 shows the 95% confidence interval of the median difference of each group from the plasma (control) group.

Comment

Pericardial fluid is an ultrafiltrate of plasma with similar electrolyte concentrations but only one-third the protein concentration. Free fluid within the pericardium is secreted by the visceral pericardium and reabsorbed by the lymphatics of the parietal pericardium; it is found at relatively constant volumes of less than 50 mL. It is our subjective interpretation that some cardiovascular surgeons do not aspirate pericardial or pleural fluids into autotransfusion scavenging systems for fear of causing hemolysis. The argument that pericardial fluid causes hemolysis stems from an early report by Morris and associates [3] that suggested that direct trauma to the red corpuscle may cause some disruption, but that indetermi-

nate properties of pericardial fluid were the major determinants of hemolysis. The report was based on indirect clinical observations that perfused patients' serum free hemoglobin concentrations were higher off bypass when compared with levels measured immediately before the discontinuation of extracorporeal support. Blood scavenged from the pleural and pericardial cavities immediately before coming off bypass was implicated. Laboratory evaluation of the blood in the pleural and pericardial cavities showed evidence of significant hemolysis (pericardial cavity more than pleural). Morris and associates' report was supported by subsequent authors. Siderys and colleagues [5] compared membrane and bubble oxygenation in cardiopulmonary bypass patients and additionally addressed the question of the role of blood contact with the pericardium in producing hemolysis. They developed a method of specifically aspirating the pericardial and pleural cavities of their contained blood, centrifuged the blood cells from the plasma, decanted the plasma, and returned the cell mass to the bypass circuit. Pericardial blood was found to have a serum free hemoglobin concentration of 485 mg/dL, whereas the intracardiac sump and pump blood showed 17 mg/dL and 15 mg/dL, respectively ($n = 6$ patients). Nuclide tagged cells from the pericardial and pleural fluids showed a normal postoperative life span.

Previous authors based their comments on indirect observations and did not discuss specific properties of local tissues (pleura, pericardium, muscle, fat) that may contribute to hemolysis by unavoidable direct contact with blood during surgical procedures. Our study was designed to establish if indeed pericardial fluid causes hemolysis and, additionally, if other autogenous local tissues may be implicated as playing a more important role in red cell destruction.

We were unable to demonstrate statistically significant hemolysis by incubating fresh whole blood and pericardial fluid. In fact, in 6 of 10 patients the serum free hemoglobin concentration of pericardial fluid incubations was less than that of controls. Hemolysis within incubated specimens of pericardium, vein, and fat were higher than controls but did not achieve statistical signif-

Table 2. Ninety-five Percent Confidence Intervals of Median Difference Between Serum Free Hemoglobin Concentrations of Each Site and Control Group

Site	95% Confidence Interval (mg/dL)
Muscle	3.6-341.4
Pericardium	-4.3-82.8

Fat	-5.4-42.7
Hemolyzed RBC	3,237-7,156

RBC = red blood cells.

icance. These are tissues that are subjected to comparatively less traumatic dissection than pleura or skeletal muscle encountered during mammary artery mobilization. The levels of hemolysis in muscle and pleura incubations did achieve statistical significance. Clinically, we suggest that minimal and gentle handling of pleura and muscle during dissection of the mammary artery pedicle may reduce liberation of tissue factors responsible for hemolysis. We do not suggest that blood collected within the pleura should be discarded, as current blood salvage technology includes cell washing systems that may remove hemolytic tissue factors.

Hemolysis often accompanies clostridial infections [6]. Clostridia-associated hemolysis results from lysolecithin activity [7]. Lysolecithins are a release product of damaged cell membranes that may also be responsible for red cell disruption after surgical procedures. Lysolecithins are naturally occurring hydrolytic products of phospholipase A₂ that are found within cell membranes and function as modulators of membrane biologic functions. These products are usually found in low concentrations in the serum. When released from damaged membranes they are quickly deactivated by binding to serum albumin and phospholipase B₂. When unbound serum lysolecithins contact the red corpuscle membrane they enter the membrane and act as a detergent to remove membrane lipids and also activate complement. These activities create openings within the corpuscle membrane large enough to allow electrolyte and fluid influx. The resultant solute flow causes an osmotic hemolysis [8].

The pleura generally does not undergo extensive dis-

section. We are unable to conjecture as to a property of pleural tissue that may be responsible for hemolysis. The patient undergoing cardiac revascularization is subject to dissection of numerous types of tissue and cardiopulmonary bypass, both of which may play a more prominent role than pericardial fluid in postoperative hemolysis.

Preimplantation Alteration of Adenine Nucleotides in Cryopreserved Heart Valves

Patrick W. Domkowski, MS, Robert H. Messier, Jr, MD, Donald G. Crescenzo, MD, Hamdy S. Aly, MD, PhD, Anwar S. Abd-Elfattah, PhD, Stephen L. Hilbert, PhD, Robert B. Wallace, MD, and Richard A. Hopkins, MD

Georgetown University School of Medicine, Washington, DC; Medical College of Virginia, Richmond, Virginia; and Food and Drug Administration, Rockville, Maryland

To assess the initial metabolic phase of cellular injury from cardiac valve processing, high-energy phosphate concentrations were analyzed in valve leaflets subsequent to critical processing steps. Using a porcine model, valves were processed in a manner identical to human homografts, with 58 randomly assigned to five groups representing distinct preparation phases. Group I (controls) sustained 40 minutes of warm ischemia concluded by liquid nitrogen immersion. Remaining groups similarly endured 40 minutes of ischemia, but were subsequently prepared according to stepwise design: II, warm ischemia + 24 hours of 4°C ischemia; III, warm ischemia + 24 hours of 4°C antibiotic disinfection; IV, warm ischemia + 24 hours at 4°C (without antibiotics) + cryopreservation (–1°C/min cryoprotected freezing); and

V, warm ischemia + disinfection + cryopreservation. At each regimen's conclusion leaflet extracts were assayed by high-performance liquid chromatography for high-energy adenine nucleotides (adenosine triphosphate, adenosine diphosphate, adenosine monophosphate) and catabolites. A 47% and 86% decrease in cellular adenosine triphosphate level was observed in group III and group V leaflets, respectively. The level of total adenine nucleotides was maintained up to cryopreservation; thereafter a 74% decrease was noted. Catabolite analysis confirmed incomplete degradation of adenine nucleotides indicating cellular metabolic resilience throughout standard homograft preparation in valves previously exposed to 40 minutes of warm ischemia.

(*Ann Thorac Surg* 1993;55:413–9)

Congenital and acquired cardiac valvular pathology continues as a prevalent clinical problem, often requiring prosthetic replacement. Because of the morbidity associated with the conferred "prosthetic valve disease," transplanted human valves are under increasing scrutiny as they have demonstrated certain specific advantages over xenograft and mechanical replacement heart valves [1]. With increased utilization, those factors potentially influencing prolonged valve durability, the major controversial issue, remain incompletely characterized. It has been proposed by some that such determinants may be related to the postimplantation cellular integrity of homograft leaflet fibroblasts [2–4].

Since the initial homograft aortic valve replacements by Ross and Barratt-Boyes in 1962 [5, 6], many methods have been employed for preparation before storage of such tissue. Historically, these have included various methods of chemical disinfection and sterilization including high-concentration antibiotics, β -propiolactone, ethylene ox-

ide, irradiation, and glutaraldehyde treatment. Most have been demonstrated to damage the tissue and thereby negatively influence long-term homograft durability [7–9]. Conversely, less rigorous techniques such as maintenance in culture medium (4°C) for up to 6 weeks have provided satisfactory results [10–12]. At present, however, the majority of harvested human valves are disinfected using antibiotic formulations having low toxicity and preserved by controlled-rate freezing (–1°C/min) with 10% dimethylsulfoxide as a cryoprotectant [13, 14].

Cryopreservation is a well-defined and reproducible technique [15], but other "preimplantation processing" steps occurring between valve harvest and implantation are less uniform. Details of one effective method include a rinsing of the procured valve in saline solution and storage in cold (4°C) nutrient medium for 24 hours, during which transport to processing facilities and antibiotic disinfection are usually accomplished. Valves are then cryopreserved as described and maintained in vapor phase liquid nitrogen until the time of transplantation, when they are thawed by means of a dilutional warming procedure in the operating room. Each step between donor death and implantation retains a potential for homograft alteration through injury to the cellular and matrix components. Morphologic criteria and in vitro cell viability assays have been used as a means of monitoring the effects of processing on the valvular tissue [3]; we were interested in quantitating high-energy phosphate

concentrations as a function of the various processing steps. Intracellular concentration changes of adenine nucleotides essential for anabolic cellular function may serve as an estimate of the metabolic status of the cell. This type of metabolic assay of high-energy phosphate measures ischemic injury presumably during a prelethal injury phase. This may function as an initial measurement of ischemic stress, rather than using a less sensitive indicator of frank cell death. The purpose of this experiment was to accurately measure these phosphorylated adenine nucleotides and their products of catabolism, thereby evaluating the extent of such injury occurring consequent to cold ischemia, antibiotic disinfection, and cryopreservation.

Material and Methods

Animal Preparation

Fifty-eight semilunar cardiac valves were obtained from 9-month-old female Yorkshire and Poland China swine after a 40-minute period of corporeal warm ischemia between death of the animal and cardiectomy at the slaughterhouse. Aortic and pulmonary valve conduits were dissected, roots opened between adjacent cusps, and the leaflets subjected to vigorous scraping with a rubber policeman to remove endothelium. Random scanning electron microscopy was performed to verify endothelium removal. The excised leaflets were either stored in liquid nitrogen (-190°C) or refrigerated (4°C) as defined by the experimental protocol.

Experimental Groups

Group I ($n = 12$) leaflets were immediately immersed in liquid nitrogen after harvest (ie, control; 40-minute warm ischemic time) to establish baseline adenine nucleotide concentrations. Group II ($n = 12$) leaflets were placed in serum-free RPMI 1640 nutrient medium (Gibco Co, Grand Island, NY) at 4°C for 24 hours (cold ischemic time; analogous to cold transport of donor tissue to processing centers, but in the absence of antibiotics by design) followed by rapid freezing by immersion in liquid nitrogen. Group III ($n = 11$) leaflets were subjected to 4°C antibiotic disinfection (cold disinfection time, virtually analogous to clinical protocol) followed by immersion in liquid nitrogen. The antibiotic formulation consisted of a serum-free RPMI 1640 nutrient media solution containing cefoxitin, $240\text{ }\mu\text{g/mL}$; lincomycin, $120\text{ }\mu\text{g/mL}$; polymyxin B sulfate, $100\text{ }\mu\text{g/mL}$; and vancomycin, $50\text{ }\mu\text{g/mL}$ [15]. Group IV ($n = 12$) was subjected to cold ischemia (identical to group II valves, 24 hours at 4°C , in antibiotic-free media) but then cryopreserved as follows: 10% each of dimethylsulfoxide and fetal calf serum in RPMI 1640, frozen at a rate of $-1^{\circ}\text{C}/\text{min}$ to -60°C (CryoMed 1010 Micro computer), and stored in vapor phase liquid nitrogen (-190°C) (CryoMed freezer model CMS-450A, New Baltimore, MI) [15]. Group V ($n = 11$) leaflets were subjected to all of the processing steps, modeling a completed homograft preparation with brief warm ischemia (ie, 40 minutes of warm ischemia, 24 hours of cold antibiotic disinfection, and cryopreservation). Leaflets were thawed in single-valve trileaflet sets, and one cusp

was randomly selected for analysis of all adenine nucleotide metabolites by high-performance liquid chromatography.

Extraction Procedure

Using cold (4°C) instruments to manipulate the tissue, the selected leaflet from each valve was homogenized by hand for 30 minutes at 10°C in 12% trichloroacetic acid solution. The mixture was separated by centrifugation (10 minutes, 3,000 rpm) and the soluble extract removed and neutralized using a tri-*n*-octylamine:freon (1:2) mixture. After vortexing, the organic phase was separated by centrifugation (10 minutes, 3,000 rpm) and stored in 1.5-mL polypropylene microcentrifuge tubes (Baxter, McGaw Park, IL) at -70°C . The postextraction pellets of denatured leaflet protein were dissolved in 0.6 N sodium hydroxide for protein determination according to the method described by Lowry and associates [16] (Gilford Response UV-VIS spectrophotometer [Oberlin, OH] at 725 nm).

High-Performance Liquid Chromatography Analysis

Aliquots ($80\text{ }\mu\text{L}$) were loaded onto a Waters Intelligent Sampler Processor model 710B high-performance liquid chromatography column (Waters Associates, Milford, MA). A solvent delivery system model 6000A (Waters Associates) along with a solvent selector model 101 (Alltech Associates, Deerfield, IL) was used. Step gradient separation of the adenine pool metabolites (adenosine triphosphate [ATP], adenosine diphosphate [ADP], adenosine monophosphate [AMP], oxidized form of nicotinamide adenine dinucleotide [NAD^+], adenosine, inosine, hypoxanthine, and xanthine) was achieved using a NOVA-Pak-A (C18; $5\text{-}\mu\text{m}$ particle size; $10 \times 8\text{ mm}$) chromatographic column inside a radial compressor module model RCM 100 (Waters Associates) (Fig 1). Ammonium phosphate (100 mmol/L ; pH 5.5) was used to elute ATP, ADP, uric acid, hypoxanthine, and xanthine; NAD^+ was eluted with 7% methanol; and inosine and adenosine were eluted with 40% methanol. The adenine pool metabolites were integrated and quantitated to external standards through a visible/ultraviolet detector model 490 and a data module model 730 (Waters Associates). Retention time, peak area, and amounts of all eluted adenine metabolites were recorded on each chromatogram and normalized to the average concentration of protein in the units of adenine metabolite per milligram of protein $\pm$ standard error of the mean. Chemical reagents and buffers were purchased from Sigma Chemical Company (St. Louis, MO). High-performance liquid chromatography-grade ammonium phosphate and methanol were purchased from Fisher Scientific (Fair Lawn, NJ). Distilled and deionized water was processed through the Milli-Q System Millipore (Bedford, MA).

Statistical Analysis

The statistical analysis program SAS (Statistical Analysis System Institute, Cary, NC) processed on an IBM 386 computer was used to determine statistical significance, where p was less than 0.05 using a one-way analysis of

Fig 1. Representative peaks of adenine nucleotide pool metabolites as generated by step-gradient high-performance liquid chromatographic elution. Retention time, peak area, and amounts of each metabolite are recorded from each chromatogram. (ADEN = adenosine; ADP = adenosine diphosphate; AMP = adenosine monophosphate; ATP = adenosine triphosphate; HX = hypoxanthine; INO = inosine; NAD = nicotinamide adenine dinucleotide, oxidized form; X = xanthine.)

variance between all possible combinations of each step of the experimental model. A Scheffé's multiple comparison procedure was used to identify significant differences between treatment groups.

Results

Valve leaflets (excluding endothelium) were analyzed after each processing step of a representative homograft valve cryopreservation protocol to quantify the following metabolites: ATP, total adenine nucleotides (TAN = AMP + ADP + ATP), and total diffusible purines (TDP =

Fig 2. Progressive degradation of adenosine triphosphate (ATP) existing at the completion of each processing phase: (I) warm ischemia, (II) cold transport, (III) antibiotic disinfection, (IV) cryopreservation, and (V) cryopreservation with antibiotics. adenosine + inosine + hypoxanthine + xanthine) (Table 1, Figs 2-4).

Group I: 40 Minutes of Warm Ischemia (Control)

After 40 minutes of warm ischemia 12 randomly assayed leaflets contained the following baseline concentrations: ATP = 1.78 ± 0.25 nmol/mg protein, TAN = 2.59 ± 0.33 nmol/mg protein, and TDP = 3.51 ± 0.41 nmol/mg protein (see Figs 2-4). Values for all metabolites are listed in Table 1.

Group II: 40 Minutes of Warm Ischemia + 24 Hours of 4°C Ischemia (No Antibiotics)

A 17% reduction in ATP (see Fig 2) was observed in group II leaflets (1.48 ± 0.12 nmol/mg protein) as compared with group I levels, indicative of some ATP degradation induced by this step. In addition, there was an 8% increase in TAN (2.81 ± 0.34 nmol/mg protein) (see Fig 3) and a 6% increase in TDP (3.75 ± 0.87 nmol/mg protein) (see Fig 4) as compared with group I. This commenced a trend of ATP degradation to lower energy adenine nucleotides

ADP = adenosine diphosphate; AMP = adenosine monophosphate; ATP = adenosine triphosphate; NAD⁺ = nicotinamide adenine dinucleotide, oxidized form; WIT = warm ischemia.

Fig 3. Total adenine nucleotides (TAN) existing at the completion of each processing phase: (I) warm ischemia, (II) cold transport, (III) antibiotic disinfection, (IV) cryopreservation, and (V) cryopreservation with antibiotics. (* $p < 0.05$ versus groups I, II, and III.)

and ultimately to purine byproducts (both TAN and TDP were increased). However, statistical significance was not reached by this group of valves.

Group III: 40 Minutes of Warm Ischemia + 24 Hours of 4°C Ischemia With Antibiotics

Antibiotic disinfection resulted in a 49% reduction (see Fig 2) in ATP with respect to control leaflets (0.91 ± 0.13 nmol/mg protein; $p \leq 0.0001$ versus group I). However, TAN concentrations in group III (2.28 ± 0.48 nmol/mg protein) were not significantly reduced. It should be emphasized that through the completion of the antibiotic step, total high-energy phosphate metabolites (TAN) were statistically maintained at baseline 40-minute levels (see Fig 3), indicating that during these stages ATP degradation proceeds mainly to its lower energy phosphates (ie, ADP and AMP). However, levels of diffusible purines were 55% higher (7.83 ± 1.84 nmol/mg protein) than in group I ($p = 0.0006$) (see Fig 4). This accumulation of byproducts is consistent with degradation of ATP to TAN and partial TAN degradation to adenosine, inosine, hypoxanthine, and xanthine.

Group IV: 40 Minutes of Warm Ischemia + 24 Hours of 4°C Antibiotic-Free Ischemia + Cryopreservation

The consequences of cryopreservation were evaluated in groups IV and V, which differed by the presence or

Fig 4. Total diffusible purines (TDP) at the completion of each phase of cardiac valve transplant preparation: (I) warm ischemia, (II) cold transport, (III) antibiotic disinfection, (IV) cryopreservation, and (V) cryopreservation with antibiotics. (* $p < 0.05$ versus groups I, II, and V by analysis of variance.)

absence of antibiotics. In group IV, the valves exposed to cryopreservation without antibiotics, there was a significant depletion of ATP by 74% (0.46 ± 0.11 nmol/mg protein) compared with control ($p \leq 0.0001$) (see Fig 2). The 69% reduction ($p = 0.0001$) in ATP between groups II and IV (see Fig 2) quantitates the effect of cryopreservation and warm and cold ischemia without exposure to antibiotics. Similarly, cryopreservation without antibiotics effected a 66% TAN depletion from baseline (0.87 ± 0.15 nmol/mg protein) (see Fig 3). With the addition of cryopreservation to 24 hours of cold ischemia (group IV), there was a 69% diminution ($p = 0.0001$) in TAN from antibiotic-free cold ischemia levels (group II). There was a significant change in total diffusible purines (1.24 ± 0.49 nmol/mg protein) in group IV ($p < 0.05$ versus baseline).

Group V: 40 Minutes of Warm Ischemia, 24 Hours of 4°C Antibiotic Disinfection, and Cryopreservation (Complete Cryopreservation Protocol)

Analysis of ATP in group V (0.25 ± 0.04 nmol/mg protein) measures the cumulative effects of all steps involved in the preparation of clinical homograft cardiac valves. There was an 86% ($p = 0.0001$) and 83% ($p = 0.0001$) reduction in ATP as compared with baseline (group I) and 24 hours of cold ischemia without antibiotics (group II), respectively (see Fig 2). Cells in leaflets exposed to both antibiotics and cryopreservation demonstrated a 73% reduction in ATP ($p = 0.0001$) versus leaflets experiencing 24 hours of cold ischemia with antibiotics (group III) (see Fig 2).

The effect of all steps (group V) on TAN levels (0.68 ± 0.09 nmol/mg protein) was similar to that seen with group IV. Concentrations of AMP, ADP, and ATP in the fully processed leaflets demonstrated a 74% ($p = 0.0001$) reduction as compared with group I (see Fig 3).

The total diffusible purine concentration in fully processed leaflets (3.56 ± 0.82 nmol/mg protein) was 55% less than the purine level in leaflets assayed after antibiotic disinfection alone (see Fig 4). The NAD^+ levels remained essentially unchanged (0.49 ± 0.06 nmol/mg protein) until the cryopreservation steps, which resulted in a slight reduction.

Comment

This study of porcine cardiac valves was designed to mimic favorable harvest conditions in which the warm ischemic time was limited to 40 minutes, correlating with a brief period between cessation of donor heartbeat and procurement, such as might occur in a multiple organ harvest setting. Experimental tissue exposed to this degree of ischemia conveniently served as control groups with which to compare metabolite levels after later pre-implantation processing steps. Twenty-four hours of cold ischemia did not cause reductions in total high-energy phosphate concentrations from baseline (see Fig 3). However, 24 hours of cold ischemia resulted in a decrease in the ATP level that, although not statistically significant, was subsequently observed throughout processing. This finding indicates that although the ATP level is diminished at this stage, the majority of degradation occurs

only through to ADP and AMP (reflected in total adenine nucleotide concentrations; confirmed by the measured increases in ADP and AMP) due to incomplete breakdown of ATP or partial restoration by alternate pathways. The purpose of this particular experimental grouping, however, was to differentiate the cold ischemic effects alone (group II) from cold ischemia combined with disinfection (group III).

Antibiotics and Processing-Associated Injury

Many aggressive antibiotic regimens that include antifungal and high-dose antibiotic mixtures have been detrimental to fibroblast viability [17], but antibiotic combinations similar to the one employed in this study appear relatively benign as demonstrated by tissue culture and proline uptake assessment [18-20]. Independent of antibiotic toxicity [21, 22], this study has substantiated that metabolic depletion is, in fact, occurring during 24 hours of cold ischemia and antibiotic disinfection. However, in this study the majority of ATP degradation occurring during antibiotic disinfection generates only to ADP and AMP, which is noteworthy considering that it is the conservation of total high-energy phosphates (not ATP alone) that is critical to a cell's ability to maintain basal function and integrity [23]. Such changes are potentially reversible (eg, conversion of ADP and AMP to ATP) and appear to be likely due to the ischemia associated with the time necessary for disinfection rather than chemical injury. The effect of disinfection disappears when comparing cryopreservation with and without antibiotics, because cryopreservation after disinfection results in an additional 46% depletion of ATP. Regardless of whether prior antibiotic disinfection treatment is used, apparently the cryopreservation phase is responsible for the largest decrease in ATP. This information can be used to develop disinfection strategies that may be even less metabolically costly. Total avoidance of antibiotic disinfection with the subsequent enhanced risk for transmission of infectious disease to the recipient does not appear to be worth the minimal "gain" of reduced metabolic cellular leaflet injury and its theoretical effect on long-term performance.

DMSO Cryopreservation and Cellular Metabolic Injury

With subsequent cryopreservation, significant reductions in high-energy phosphates were observed. Cryopreservation alone, subsequent to only warm ischemia and 24 hours of 4°C ischemia without antibiotics, was responsible for a substantial depletion of ATP (74%) (see Fig 2), which was greater than that imparted by cold ischemia (17%) or cold disinfection (47%). The effects of all preprocessing steps were synergistic in the diminution of adenine nucleotides. Nevertheless, leaflet cells still retained measurable amounts of high-energy phosphates after all of the processing steps (see Fig 3).

Metabolic Depletion, Cell Injury, Viability, and Durability

Determination of the relationship between valvular leaflet fibroblast viability and the long-term function and durability of homografts has been the focus of a few investi-

gations and numerous postulations [17, 24, 25]. Before this interesting question can be addressed, the initial response of the leaflet fibroblast cell population to ischemia and subsequent processing steps must be defined. Adenine nucleotide quantitation is not by itself a viability assay; however, it is a specific indicator of the overall metabolic state of the leaflet fibroblast cell population. Our data define a progressive diminution of high-energy phosphate with each step of preimplantation processing. It is reasonable to assume that as these nucleotides are increasingly depleted, a percentage (without attempting to assign a value) of fibroblasts will lose their ability to structurally maintain cell membranes, thus leading to irreversible injury. It is possible that only after relatively complete depletion of high-energy phosphates in the cell population (which this study did not find, even in the fully processed groups) will irreversible metabolic injury be manifest in the majority of fibroblasts. Unlike specific morphological assays [26], which examine irrefutable structural criteria for injury or death of fibroblasts, the aim of this investigation was to delineate the energy reserve of the leaflet fibroblast population. Few studies have carefully analyzed the early injury response (before irreversible cell injury), a period when such insults may be reversible and responsive to technical modifications, thereby potentially mitigating later effects on ultimate viability. Such changes in high-energy phosphate status might also precede reductions in energy-dependent cell functions such as proliferation, protein transport, and synthetic activity [19].

The hypothesis that cellular viability is a critical determinant of long-term clinical performance rests on the notion that it is the extent of cellular viability *at the time of implantation* that is the key issue [4]. If harvesting and processing protocols are to be designed to maximize cellular viability, then studies like this one are fundamental to understanding the effects of preimplantation processing on heart valve tissue [26-28]. An alternative concept might be that it is the extent of functional viability (ie, fibroblast capable of proliferation and structural protein synthesis) some weeks or months after transplantation that is critical to enhancing valve durability. This being the case, processing methods that result in cells that not only "appear" viable but that have significant metabolic reserve with which to weather the peritransplantation stress could lead to better leaflet fibroblast functional recovery.

High-Performance Liquid Chromatography

High-performance liquid chromatography assays have been employed to quantitate adenine nucleotide concentrations in myocardial cells after ischemia and reperfusion injury [29]. This study demonstrates the feasibility of this method for detecting nanomolar concentrations of the adenine nucleotide metabolites in cardiac valvular leaflets as well. Other methods for adenine nucleotide determination include enzymatic analysis and nuclear magnetic resonance; however, the former depends on generation or consumption of a substrate in subcellular reactions, whereas the latter requires fairly large samples [30, 31].

Fig 5. Degradation of adenosine triphosphate (ATP) to its lower energy metabolites and constitutive purine bases. Circled numbers indicated principal enzymes responsible for ATP catabolism: 1 = ATP kinases, 2 = adenylate kinase, 3 = cytosol 5'-nucleotidase, 4 = adenosine deaminase, 5 = purine nucleoside phosphorylase, 6 = xanthine oxidase, 7 = xanthine oxidase. (ADP = adenosine diphosphate; AMP = adenosine monophosphate.)

The progression of biochemical changes in the leaflet fibroblasts has been examined with proton (^1H) and phosphorous (^{31}P) magnetic resonance spectroscopy, and demonstrated a time-dependent depletion of ATP stores reflected by an increase in inorganic phosphate; after 2 hours of harvest-related ischemia, increases in lactate concentration were measured by the nuclear magnetic resonance technique indicating the onset of anaerobic metabolism [30]. These data are quite consistent with our high-performance liquid chromatography results.

An advantage of the high-performance liquid chromatography technique resides in its utility for analysis of the entire high-energy phosphate pool in a "snapshot" fashion throughout the degradatory cascade [32] (Fig 5). All catabolism reactions up to and including the production of adenosine are completely reversible and allow for the possibility of adenosine phosphorylation into a high-energy metabolite and reutilization. Conversely, the freely diffusible purine inosine cannot be converted to adenosine because mammalian cells do not contain appreciable amounts of the necessary inosine kinase [31]. Phosphorylated moieties are restricted to the intracellular milieu.

The remaining components of the adenine nucleotide pool, the diffusible purine bases adenosine, inosine, hypoxanthine, and xanthine, were quantitatively assessed in this study to confirm the high-energy phosphate degradation seen. As total high-energy phosphates are depleted, there should be a concomitant increase in total purine concentrations. This phenomenon was observed through the antibiotic phase in our study. Compared with baseline purine levels, leaflets exposed only to cold ischemia versus those subjected to cold ischemia plus antibiotic disinfection experienced a 6% and 55% increase in purine levels, respectively (see Fig 4). Thus, the greatest increase in TDP was experienced by those groups with the longest decrease in high-energy phosphates. This confirms a certain portion of the TAN pool is in fact proceed-

ing to various metabolites on the lower end of the degradatory pathway (see Fig 5). It must be noted, however, that this linear increase in TDP was blunted at the cryopreservation step. The dilutional liquid media technique for removal of dimethylsulfoxide during thaw may be responsible for a "wash out" of these bases as seen in groups IV and V. Furthermore, the mandatory immersion during disinfection may also account for the lower TDP levels found in both nonantibiotic and antibiotic-treated cryopreserved leaflets.

Time- and Process-Dependent Depletion of High-Energy Adenine Nucleotides

The ATP and TAN concentrations measured at the completion of each step of the cryopreservation process indicate progressive metabolic insult to the valvular leaflet cells. This injury becomes quantitatively important at the antibiotic disinfection step when considering only ATP, whereas TAN depletion does not become significant until later, after cryopreservation. These methods analyze and characterize metabolic effects, which are potentially reversible and thus may be useful in monitoring technological modifications in homograft processing.

These detailed biochemical studies suggest that cardiac valvular leaflet fibroblasts are remarkably metabolically resilient and withstand significant perturbation of energy metabolism during processing. The cell population demonstrates measurable energy reserve when the obligatory processing stages are preceded by relatively short harvest-associated warm ischemia (40 minutes) [33]. The observed metabolic response to the summation of ischemia, antibiotic disinfection, and cryopreservation suggests that these leaflet matrix cells retain reduced but not exhausted intracellular high-energy adenine nucleotide stores. Therefore, at the time of implantation, the population of matrix leaflet cells within the homograft cusps, although significantly altered, are not completely metabolically exhausted by the processing steps inherent in current cryopreservation methods.

Interstitial pH During Myocardial Preservation: Assessment of Five Methods of Myocardial Preservation

William M. L. Neethling, PhD, Johannes J. van den Heever, BScHonn,
Susan Cooper, MSc, and Johannes M. Meyer, MMed

Departments of Cardiothoracic Surgery and Anatomical Pathology, Medical School, University of the Orange Free State, Bloemfontein, Republic of South Africa

We investigated changes in myocardial pH during cardioplegic arrest with five methods of preservation at 15° ± 1°C. Twenty-five dogs were subjected to cardiopulmonary bypass for 150 minutes. Group I (control) had hypothermia only. Group II received THAM-buffered blood cardioplegia, group III a bicarbonate-buffered blood cardioplegic solution, group IV infusions of hyperkalemic blood, and group V oxygenated St. Thomas 2 solution. After 120 minutes of ischemia, interstitial pH in group I was markedly depressed (6.4 ± 0.07 ; $p < 0.01$). The pH in groups II and IV was well maintained (7.23 ± 0.05 and 7.27 ± 0.07) and differed significantly ($p < 0.05$) from that of the remaining groups. The pH in groups III and V was less well maintained (7.14 ± 0.02 and 7.01 ± 0.05), with no significant difference ($p > 0.05$) between

these two groups. Postreperfusion functional recovery after 45 minutes was $24\% \pm 6\%$ in group I, $92\% \pm 3\%$ in group II, $82\% \pm 5\%$ in group III, $84\% \pm 4\%$ in group IV, and $66\% \pm 6\%$ in group V. Creatine kinase levels were significantly ($p < 0.01$) increased and ultrastructural damage was more prominent in group I compared with the remaining groups. Myocardial water content significantly increased in all groups. We conclude that a strongly buffered blood-based cardioplegic solution is more effective in preventing interstitial acidosis during moderate hypothermia and that maintenance of an optimal tissue pH plays an important role in postischemic functional recovery.

(*Ann Thorac Surg* 1993;55:420-6)

Myocardial arrest is commonly used as an adjunct in cardiac operations [1]. Since the introduction of elective cardioplegic arrest by Melrose and his colleagues [2] in 1955, different methods and techniques have been advocated for clinical use during cardiac operations [3-7]. The relative efficacy of these methods in achieving optimal protection of the myocardium has been debated in numerous animal and clinical studies [8-11]. Most of these studies have demonstrated the advantages of sanguineous over asanguineous solutions in preserving myocardial metabolism and ultrastructure [12-15]. In contrast, some clinical studies show no difference between sanguineous and asanguineous solutions, leading to an unsettled controversy [16-18].

During myocardial anaerobiosis the production of high-energy phosphates from glycolysis is not sufficient to cover the myocardial energy deficit that develops with progressive duration of ischemia [19]. The decrease in high-energy phosphates is accompanied by the accumulation of hydrogen ions and lactate [20]. The increased intracellular hydrogen ion concentration and the resultant

tissue acidosis finally leads to a self-inhibition of anaerobic glycolysis [21]. Administration of cardioplegic solutions and hypothermic techniques can delay the metabolic consequences of ischemia, but only for a limited time.

In 1975 Bretschneider and his colleagues [22] proposed the buffering of cardioplegic solutions as a method to increase the ischemic tolerance of the myocardium during elective arrest. This proposal was based on the possibility that buffering could facilitate the washout of hydrogen ions and lactate, thus enabling glycolysis to continue. Recent work by Del Nido and associates [23] demonstrated the effectiveness of histidine-buffered and blood-based solutions in maintaining interstitial pH levels close to preischemic levels.

As it is impossible in the clinical setting to monitor the decrease of myocardial energy production continuously or intermittently, the maximum period of arrest believed to be safe for an individual patient is an arbitrary estimate, based on clinical experience and experimental studies.

In the present study, we assessed the influence of five methods of myocardial preservation on myocardial tissue acidosis during induced myocardial ischemia. The five methods were hypothermia, THAM (Tris-hydroxymethyl-aminomethane)-buffered blood cardioplegia, bicarbonate-buffered blood cardioplegia, hyperkalemic blood, and oxygenated St. Thomas 2 crystalloid solution.

NaHCO₃ = sodium bicarbonate; THAM = Tris hydroxymethyl aminomethane.

Material and Methods

Animals

Twenty-five adult beagle dogs, matched for weight (18 to 22 kg) and age, were obtained from the animal care facilities of the University of the Orange Free State. All animals received humane care in compliance with the "Principles of Laboratory Animal Care" (National Society for Medical Research) and the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Cardioplegic Solutions

The formulation of the different cardioplegic solutions is listed in Table 1. Hypothermia alone, at 15° ± 1°C, was used as a control. The THAM-buffered and bicarbonate-buffered cardioplegic solutions were prepared by mixing freshly oxygenated blood from the perfusion circuit with the corresponding crystalloid solutions (1:1). The hyperkalemic blood solution was prepared by adding potassium chloride to freshly oxygenated blood to a concentration of 12 to 14 mmol/L. The St. Thomas 2 solution was made up in the conventional composition [24] and oxygenated with 95% oxygen and 5% carbon dioxide.

Interstitial pH Measurement

Myocardial interstitial pH was measured with a combined hydrogen ion-sensitive miniature glass electrode (Micro-electrodes Inc, Londonderry, NH) housed in the beveled end of a 21-gauge stainless steel needle with an outside diameter of 0.8 mm and a length of 20 mm. A Beckman Model 4500 pH meter (Beckman Instruments Inc, Irvine,

CA) with a temperature controlled pH unit was used to continuously monitor changes in the interstitial pH during the ischemic period. The electrode was positioned at an angle of approximately 45 degrees to the epicardial surface at a depth of 6 to 8 mm.

Electrode Calibration Procedure

The miniature pH electrode was calibrated with standard laboratory buffers (BDH Chem, Poole, UK) of pH 4.00 and 7.00 at different temperatures ranging from 10° to 20°C. The mean response time to a step change in pH was 35 seconds. The electrode was calibrated before each experiment.

Myocardial Temperature Measurements

Myocardial temperature was measured continuously with thermoneedle probes (Model 6500; Mon-a-Therm Inc, St. Louis, MO) placed in the right and left ventricular muscle wall (next to the pH electrode) and the ventricular septum.

Experimental Preparation and Protocol

All animals were anesthetized intravenously with sodium pentobarbital (30 mg/kg), intubated, and ventilated with a volume-controlled Penlon 2000 respirator. Anesthesia was maintained with a mixture of oxygen and halothane (Fluothane; Wyeth-Ayerst Laboratories, Philadelphia, PA).

The left femoral artery was cannulated for monitoring systemic blood pressure, arterial blood gases, and hematocrit values. Systemic temperature was monitored with a rectal temperature probe connected to the Sarns 2200 operating console. The electrocardiogram was monitored continuously throughout the experiment.

A midline sternotomy was performed after systemic heparinization (5 mg/kg), and the aorta was cannulated with an 18F Argyle cannula. Both the superior and inferior venae cavae were cannulated and snared for venous return. The coronary sinus was cannulated through the right atrium to sample coronary venous blood samples. The azygos drainage was excluded from the venous return by passing a snare around the azygos vein. The left ventricle was vented through a 16F venous cannula positioned through a pursestring-sutured stab wound in the apex. A 10F coronary perfusion cannula was inserted into the ascending aorta to administer the cardioplegic solutions after aortic cross-clamping.

Before cardiopulmonary bypass, myocardial tissue pH, myocardial temperature, and intracardiac pressures were measured and blood samples were drawn from the femoral artery and coronary venous drainage to obtain pre-ischemic control values.

Cardiopulmonary bypass was established with the use of a Harvey (Model H-1300; William Harvey Research Corp, Santa Ana, CA) bubble oxygenator gassed with 95% oxygen and 5% carbon dioxide. Arterial pH was maintained between 7.35 and 7.45, carbon dioxide tension between 35 and 45 mm Hg, and oxygen tension greater than 120 mm Hg.

At total cardiopulmonary bypass flow, systemic hypo-

thermia was introduced and the arterial temperature lowered to 17°C. At this point, the aorta was cross-clamped for 150 minutes and the specific method of myocardial preservation was introduced. In group I, only hypothermia was used as a method of myocardial protection. Myocardial tissue temperature was controlled at $15^{\circ} \pm 1^{\circ}\text{C}$ with the aid of systemic hypothermia and topical cooling. In group II (THAM) and III (bicarbonate), 450 mL of cardioplegic solution at $14^{\circ} \pm 2^{\circ}\text{C}$ was immediately administered at a constant perfusion pressure of 80 mm Hg. Supplementary 225-mL doses of cardioplegic solution were administered every 30 minutes. In group IV, the myocardium was immediately perfused with 450 mL of cold ($12^{\circ} \pm 1^{\circ}\text{C}$), hyperkalemic, oxygenated blood (oxygen tension > 125 mm Hg) at 80 mm Hg. This procedure was repeated every 30 minutes with 225 mL of hyperkalemic blood. In group V, St. Thomas 2 solution was oxygenated with 95% oxygen and 5% carbon dioxide (oxygen tension > 400 mm Hg; pH = 7.8 at 15°C). An initial dose of 450 mL was administered at 80 mm Hg, followed by 225-mL doses every 30 minutes. The final dose was administered at 120 minutes.

Care was taken to maintain the myocardial tissue temperature at $15^{\circ} \pm 1^{\circ}\text{C}$ in all five groups for 120 minutes. Rewarming started at 120 minutes in all five groups. At 150 minutes of ischemia, normothermia ($36^{\circ} \pm 1^{\circ}\text{C}$) was accomplished and the aorta was unclamped.

After electromechanical activity resumed, stabilization on total bypass in the beating empty state was allowed for 15 minutes. Normal hemodynamic function was reintroduced and cardiopulmonary bypass stopped. Hemodynamic data were recorded, tissue pH was measured, and blood samples were taken at 15-minute intervals. At the end of the experiment, biopsy specimens were obtained for myocardial tissue water content and morphologic examination.

Hemodynamic Functional Assessment

Two 18-gauge catheters were inserted into the left atrium and left ventricle to measure corresponding pressures before and after the cardioplegic period.

Left atrial filling pressure was stabilized at 8 ± 1 mm Hg by controlling the venous return through the cardiopulmonary bypass volume. Left ventricular systolic, left ventricular end-diastolic, and left atrial filling pressure were measured before bypass (control) and at 15, 30, and 45 minutes after ischemia. Myocardial function was assessed by determination of developed pressure in the left ventricle and expressed as a percentage of the prearrest developed pressure.

Biochemical Measurement

Myocardial creatine kinase levels were measured as an indicator of metabolic changes taking place during ischemia. Samples of the coronary venous effluent were taken before bypass (control) and during every cardioplegic infusion. Analyses were done on a Baker Scientific spectrophotometer (Baker Scientific Instruments, NY) and expressed as international units per liter.

Morphological Examination

Myocardial tissue biopsy samples were taken before bypass to examine the normal morphology of the myocardium at the electron microscopic level. Additional biopsy samples taken at the end of each experiment were used to assess morphologic changes resulting from the ischemic period. A devised, semiquantitative grading system [25] based on well-established criteria of early myocardial ischemic injury was used to assess ultrastructural changes. The histologic observer was unaware of the experimental group during observation. All samples were obtained from actively contracting regions of the left ventricle within 1 cm of the pH electrode.

The samples were immediately placed in a fixative solution of 3% glutaraldehyde in phosphate buffer for 24 hours and postfixed in 1% buffered (Palade) osmium tetroxide for 1 hour. The samples were then dehydrated in a graded series of acetone, embedded in Spurr's epoxy resin and cut into 60- to 80-nm-thick sections. The sections were mounted on copper grids and routinely stained for transmission electron microscopy with uranyl acetate and lead citrate.

Myocardial Water Content

Myocardial water content was determined by weighing the biopsy samples (Mettler ME-22 analytical scale; Mettler Instrument Corp, Hightstown, NJ) before desiccation at 75°C for 24 hours. Percent water content was calculated as: $100 \times (\text{wet weight} - \text{dry weight})/\text{wet weight}$.

Statistical Analysis

All values are expressed as mean $\pm$ standard error of the mean. The data were analyzed with a one-way analysis of variance, and differences between groups were identified with Tukey's "Studentized range." A p value of less than 0.05 was considered significant.

Results

Myocardial Temperature

Preischemic left ventricular temperatures were similar in all five groups ($37^{\circ} \pm 1.23^{\circ}\text{C}$). From 0 to 120 minutes of ischemia, temperatures ranged from $15.01^{\circ} \pm 1.32^{\circ}\text{C}$ up to $16.06^{\circ} \pm 1.04^{\circ}\text{C}$ (Fig 1). No significant difference ($p > 0.05$) existed between groups. After the rewarming phase at 150 minutes of ischemia, the ventricular temperatures ($36^{\circ} \pm 1^{\circ}\text{C}$) were similar in the five groups.

Myocardial pH

In the entire group, the interstitial pH rose from 7.12 ± 1.02 to 7.25 ± 1.3 as systemic hypothermia of 17°C was reached. After cross-clamping, there was a progressive decrease in interstitial pH in group I, in which hypothermia only was used. In groups II to V an immediate increase in interstitial pH followed the infusion of the initial dose of cardioplegia (Fig 2).

Thereafter, pH levels progressively decreased in all five groups during the 30-minute interval, resulting in a pH of 6.71 ± 0.18 in group I, 7.17 ± 0.04 in group II, 7.11 ± 0.05 in group III, 7.06 ± 0.07 in group IV, and 7.34 ± 0.04 in

Fig 1. Myocardial temperature measured in the respective groups during 150 minutes of ischemia. All values are expressed as mean $\pm$ standard error of the mean ($p > 0.05$ for difference between groups). (Bic = bicarbonate; ST = St. Thomas; Tham = Tris hydroxymethyl aminomethane.)

group V. In group I, the pH continued to decline in a linear relationship with ischemic time.

With the infusion of the second dose of cardioplegia at 30 minutes, the interstitial pH in groups II to V rose sharply. Between 30 and 60 minutes ischemia, decline in pH levels in groups II and IV were less prominent compared with that of groups III and V.

This fluctuating pattern in interstitial pH levels continued throughout the 120 minutes of ischemia in groups II to V. At 120 minutes of ischemia, the pH in group I (6.40 ± 0.07) differed significantly ($p < 0.001$) from that of the remaining groups. The pH in group II (7.23 ± 0.05) and group IV (7.27 ± 0.07) differed significantly ($p < 0.05$) from that of group III (7.14 ± 0.02) and group V (7.02 ± 0.05).

Fig 2. Interstitial pH changes in the left ventricle recorded in all five groups during 150 minutes of ischemia ($p < 0.01$ for the difference between hypothermia and the rest of the cardioplegic groups). (Solid square = hypothermia; open square = THAM-buffered blood cardioplegia; solid triangle = bicarbonate-buffered blood cardioplegia; solid circle = hyperkalemic blood; open triangle = St. Thomas 2.)

Table 2. Left Ventricular Developed Pressure Before Ischemia and at 15, 30, and 45 Minutes After Reperfusion at a Left Atrial Pressure of 8 ± 1 mm Hg^a

Group	Before Ischemia	15 minutes	30 minutes	45 minutes
Group I	96 $\pm$ 3	24 $\pm$ 2	30 $\pm$ 6	23 $\pm$ 4
Group II	95 $\pm$ 3	69 $\pm$ 4	80 $\pm$ 8	87 $\pm$ 3
Group III	98 $\pm$ 2	65 $\pm$ 3	69 $\pm$ 6	80 $\pm$ 4
Group IV	96 $\pm$ 3	68 $\pm$ 3	74 $\pm$ 3	80 $\pm$ 6
Group V	96 $\pm$ 2	72 $\pm$ 3	66 $\pm$ 4	63 $\pm$ 4

^a Values are the mean $\pm$ standard error of the mean in millimeters of mercury; $p > 0.05$ for values before ischemia.

During the rewarming phase, the pH in group I decreased from 6.40 ± 0.07 to 6.38 ± 0.05 , in group II from 7.23 ± 0.05 to 7.12 ± 0.02 , in group III from 7.14 ± 0.02 to 7.05 ± 0.04 , in group IV from 7.27 ± 0.03 to 6.99 ± 0.04 and in group V from 7.02 ± 0.02 to 6.96 ± 0.04 .

Hemodynamic Functional Assessment

Table 2 presents left ventricular developed pressure measured before ischemia and at 15, 30, and 45 minutes after reperfusion.

Left ventricular systolic function measurements as represented by developed pressure (percent control) and end-diastolic pressure changes are shown in Figures 3 and 4, respectively. Recovery of developed pressure in group I was severely depressed (unable to be weaned from bypass) and significantly less ($p < 0.05$) than that of groups II to V during the entire period after reperfusion. No significant difference ($p > 0.05$) was noted between groups II to V 15 minutes after reperfusion. At 30 minutes after reperfusion, group II had a significant improvement ($p < 0.05$) in recovery compared with that of the remaining groups. At 45 minutes, the pattern of recovery was unchanged except that group V had deteriorated function and differed significantly ($p < 0.05$) from groups III and IV.

Fig 3. Postischemic left ventricular function expressed as a percentage of the prebypass (control) developed pressure (mean $\pm$ standard error of the mean; p values as stated in text). (Abbreviations are as in Figure 1.)

Fig 4. Left ventricular end-diastolic pressure measured at 15, 30, and 45 minutes after reperfusion (mean $\pm$ standard error of the mean; p values as stated in text). (Abbreviations are as in Figure 1.)

Preischemic left ventricular end-diastolic pressure ranged between 2.2 ± 0.9 and 3.0 ± 0.8 mm Hg in groups I to V. At 15 minutes after reperfusion, the elevated pressure in group I differed significantly ($p < 0.02$) from that of groups II to V. At 30 minutes, these pressures increased to 11.1 ± 1.0 mm Hg in group I, decreased to 3.0 ± 0.6 mm Hg in group II, and were slightly elevated in groups III to IV.

At 45 minutes, the most prominent increase in left ventricular end-diastolic pressure was noticed in group I. At the same time the left ventricular end-diastolic pressure returned to normal values in group II.

Biochemical Measurement

Preischemic myocardial creatine kinase levels were similar in all five groups (mean, 81 ± 12 IU/L). The creatine phosphokinase level was significantly ($p < 0.01$) increased in group I at 30 and 60 minutes of ischemia. No significant difference ($p > 0.05$) existed between groups II to V (Fig 5). From 90 to 120 minutes of ischemia, groups IV and V differed significantly ($p < 0.05$) from groups II and III. After rewarming at 150 minutes, a marked increase was

Fig 5. Creatine kinase levels in the coronary venous effluent (mean $\pm$ standard error of the mean; p values as stated in text). (Abbreviations are as in Figure 1.)

Fig 6. Myocardial water content measured 45 minutes after reperfusion and expressed as a percentage (mean $\pm$ standard error of the mean; $p < 0.05$ for difference between control and cardioplegic groups; $p > 0.05$ for difference between the cardioplegic groups). (Abbreviations are as in Figure 1.)

present in groups I, IV, and V. In groups II and III, the increase was less prominent.

Myocardial Water Content

Preischemic biopsy samples of the left ventricle revealed a water content of $74.0\% \pm 2.03\%$ in all five groups (Fig 6). A significant increase ($p < 0.02$) in myocardial water content was present in group I compared with the control at the end of the reperfusion period. Myocardial water content in groups II to V was $79.86\% \pm 2.85\%$, $78.15\% \pm 2.07\%$, $77.85\% \pm 1.80\%$, and $79.03\% \pm 1.99\%$, respectively ($p > 0.05$).

Morphological Examination

Tissue biopsy samples taken before ischemia indicated normal morphology of the myocytes with no ultrastructural changes (Fig 7A). After 150 minutes of ischemia and 60 minutes of reperfusion, severe ischemic injury appeared in group I. This injury was evident by marked mitochondrial swelling, disruption of the cristae, clearing of the matrix, and intracellular edema (Fig 7B). Biopsy samples taken from groups II to V appeared relatively normal with only slight ultrastructural changes. Figure 7C represents an overall view of these minor changes. Slight mitochondrial swelling, almost no ruptured cristae, and intracellular edema attest to the normal ultrastructure of these groups.

Comment

Myocardial protection afforded by hypothermic potassium-based cardioplegic solutions is well established in the experimental and clinical settings [26, 27]. Most of these solutions are formulated to retard myocardial metabolic processes in an effort to reduce the demand for high-energy phosphates and oxygen. However, these processes are not suppressed entirely, and anaerobic metabolites still accumulate [28]. Efforts to minimize the

Fig 7. (A) Ultrastructural assessment of the left ventricle, sampled before bypass at normothermia. The myocyte appears normal with normal shaped mitochondria (M), fine dispersed chromatin (C) in the nucleus, and no intramyofibrillar or intermyofibrillar edema. Glycogen granules (G) are well dispersed in the intermyofibrillar sarcoplasm. ($\times 7,540$ before 38% reduction.) (B) Ultrastructural assessment of the left ventricle, sampled 45 minutes after reperfusion in group I. Marked ischemic injury with ruptured cristae (Cr), clearing of the matrix (Mx), and severe intramyofibrillar and intermyofibrillar edema (E) is visible. ($\times 7,540$ before 38% reduction.) (C) Representative sample of the ultrastructural morphology of the left ventricle, sampled 45 minutes after reperfusion in groups II to V. Minor ultrastructural changes with only disrupted cristae (Cr) in a few mitochondria and slight intermyofibrillar edema (E) are visible. The sarcomeres (S) are relaxed, and glycogen (G) is present. ($\times 7,540$ before 38% reduction.)

accumulation of these metabolites by means of multidose cardioplegic infusion with low buffer capacity have been reported to be unsuccessful [29]. This finding was further complemented by observations by Lai and Scheuer [30] that intracellular acidosis and accumulation of lactate occur even when the myocardium is continuously perfused with hypoxic crystalloid solutions. Reports by Tait and co-workers [31] proved that multidose infusion of Bretschneider's solution was highly effective in preventing tissue acidosis for more than 60 minutes.

In this study we demonstrated the advantage of an effective buffer over that of a weakly buffered cardioplegic solution at moderate hypothermic conditions. Moderate hypothermia alone proved to be unsuccessful in preventing tissue acidosis. Buffered cardioplegic solutions and nonbuffered hyperkalemic blood substantially altered myocardial tissue acidosis. The superior effect of THAM-buffered blood cardioplegia supports the findings of previous reports.

THAM is a strong buffer and, when combined with oxygenated blood, forms an extremely efficient buffering system in the presence of blood serum proteins and hemoglobin, a prime source of histidine. Furthermore, red blood cells contain carbonic anhydrase, which facilitates transfer of CO_2 from the tissue to the blood by creating a gradient due to rapid removal of CO_2 in the red blood cells. An added advantage of blood cardioplegia is its capacity to supply oxygen for aerobic glycolysis. The inadequacy of the bicarbonate-buffered solutions to prevent interstitial acidosis underscores the findings of Warner and associates [32].

The effective protection afforded by hyperkalemic blood can be related to the intermittent washout of H^+ ions and lactate and the excellent buffering capacity of blood during prolonged infusions. Furthermore, the oxygen supplied by the blood could entertain brief periods of oxidative metabolism during which some of the accumulated lactate can be used to produce adenosine triphosphate.

In group I, functional recovery could not be obtained. In this group and the remaining groups, functional recovery was consistent with the pH changes observed during the ischemic period. This phenomenon supports Bretschneider's hypothesis concerning the buffering capacity of a cardioplegic solution.

Although elevated creatine kinase levels did reflect the influence of ischemic injury in all five groups, no significant correlation existed between these changes and postischemic function.

The increase in myocardial water content probably reflects damage to the volume-regulating capacity of the myocardial cells during the ischemic period. The significant increase in myocardial water in group I emphasizes the protecting effect of a buffered solution during ischemia at moderate hypothermic conditions.

The ultrastructural changes seen in the different groups complemented the aforementioned findings. In group I, extreme intracellular edema and cell disarrangement were evident due to the increased myocardial water content. Normal ultrastructure found in the remaining groups correlates well with postreperfusion functional recovery.

In conclusion, moderate hypothermia alone is ineffec-

tive in preventing interstitial acidosis. The effect of strongly buffered blood-based cardioplegic solutions is superior to that of weakly buffered blood-based solutions as well as that of buffered crystalloid solutions in maintaining interstitial pH and consequently myocardial function. Interstitial pH is an indicator of the severity of progressive ischemic injury, and we suggest that continuous intraoperative interstitial pH monitoring could be of value in assessing the myocardial status at all times during this critical phase of the operation.

We gratefully acknowledge the assistance of Mr F. Potgieter and J. Brümmer at the Animal Care Unit, the assistance of our perfusionists, Mr N. Gerber and M. Mopatse, and the assistance of Prof R. B. Snowdowne in revising the manuscript.

Autologous Vein Supported With a Biodegradable Prosthesis for Arterial Grafting

Hans-Peter Zweep, MD, Shinichi Satoh, MD, PhD, Berend van der Lei, MD, PhD, Wouter L. J. Hinrichs, PhD, Freerk Dijk, Jan Feijen, PhD, and Charles R. H. Wildevuur, MD, PhD

Cardiopulmonary Surgery Research Division and Laboratory for Histology and Cell Biology, University Hospital Groningen, Groningen, and Department of Biomaterials, University Twente, Enschede, the Netherlands

To evaluate the potential of a supporting, compliant, biodegradable prosthesis to function as a temporary protective scaffold for autologous vein grafts in the arterial circulation, we implanted vein grafts into the carotid arteries of rabbits, either with (composite grafts) or without (control grafts) such a supporting prosthesis, and evaluated them up to 6 weeks. The control vein grafts showed edema and severe medial disruption with infiltration of polymorphonuclear cells on day 1. Over the study, irregular fibrocyte formation resulted in the

formation of a fibrotic vein wall. In contrast, the composite vein grafts showed preservation of smooth muscle cell layers and elastic laminae with a minor inflammatory response. Regular proliferation of fibroblasts, which in some areas were circularly oriented, was observed. We conclude that a supporting, compliant, biodegradable prosthesis can function as a protective scaffold for vein grafts in the arterial circulation, thus reducing damage to the vein graft wall and allowing gradual arterialization.

(*Ann Thorac Surg* 1993;55:427-33)

When used as an arterial substitute, autologous vein grafts undergo degenerative changes during long-term implantation [1, 2]. This is reflected by their low long-term patency rate compared with the patency rate of arterial autografts [3]. The degenerative changes in the vein wall might have their origin in the early postoperative period. After implantation, the vein wall shows a certain degree of deendothelialization and medial damage, including disruption, fibroblast transformation of smooth muscle cells, and an inflammatory response in the vein wall with edema [4-6]. All these changes are alleged to lead to progressive fibrosis, intimal hyperplasia, and atherosclerosis of the vein wall [4, 5].

Factors such as exposure to storage media [7, 8], surgical trauma [9, 10], ischemia resulting from the interruption of vasa vasorum [5, 6], and sudden exposure to the higher arterial pressure, resulting in overstretching of the vein wall [9, 11, 12], are involved in early damage and changes of the vein wall. With special storage media and a surgical "no-touch" technique, this "iatrogenic" damage can be reduced [9, 13, 14]. However, damage to the vein graft caused by unavoidable ischemia and overstretching of the vein wall remains.

This study was undertaken to evaluate the potential of a supporting, compliant, biodegradable prosthesis to function as a temporary protective scaffold for autologous vein grafts when implanted into the arterial system. Such a protective scaffold might prevent overstretching and allow gradual adaptation to arterial pressures, ie, gradual

arterialization of the vein graft. In previous studies, we [15-19] have already demonstrated the good healing characteristics of such biodegradable prostheses.

Material and Methods

Male Chinchilla rabbits ($n = 34$) weighing 3.5 to 4 kg were used for microsurgical implantation of both a control autologous vein graft and a composite vein graft composed of autologous vein supported with a compliant, biodegradable prosthesis [15]. The side of implantation (ie, right or left carotid artery) was randomized. All animals used in this study received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH Publication No. 85-23, revised 1985).

Biodegradable Prosthesis

The compliant, biodegradable prostheses were prepared from 90/10 (wt%) polyurethane/poly-L-lactic acid. The prostheses had an internal diameter of 2.5 mm, a length of 1.5 cm, and a pore size gradient in their 0.3-mm-thick graft wall ranging from 30 μm in the inner region of the graft lattice to 100 μm in the outer region. All prostheses were sterilized with ethylene oxide and evacuated for 24 hours under high vacuum (10 to 5 mm Hg). Degradation of these prostheses is primarily a matter of fragmentation [20].

Surgical Technique

The rabbit was anesthetized by an intravenous injection of sodium pentobarbital (Nembutal; Abbott Laboratories,

Accepted for publication May 21, 1992.

North Chicago, IL; 30 mg/kg) into the marginal ear vein. The animal also was intubated, and inhalation anesthesia was accomplished with 1% halothane (Fluothane; Wyerth-Ayerst).

Under sterile conditions, a ventral midline incision was made in the neck, and the carotid arteries were carefully exposed. A 1-cm segment with a diameter of 2 mm (± 0.1 mm) from a branch of the external jugular vein at the mandibular area was used as the control vein graft. This vein graft matched in size with the carotid artery after clamp release. A 1-cm segment with a diameter of 3.2 mm (± 0.1 mm) from the internal jugular vein was used as the autologous vein graft to create the composite vein graft. All vein grafts were stored for 5 minutes in heparinized saline solution. Then all vein grafts were implanted in the carotid arteries with end-to-end anastomoses by means of standard microsurgical techniques [19].

To implant the composite vein graft, the exposed carotid artery was first clamped proximally and distally and cut in the middle. Then the distal clamp was released, and the prosthesis (internal diameter, 2.5 mm) was slipped over the distal part of the carotid artery. After implantation of the vein graft, the prosthesis was shifted back over the vein graft, including both anastomoses, thus reducing the diameter of the vein graft from 3.2 mm (± 0.1 mm) to 2.5 mm and forming a composite vein graft. Interrupted sutures of 9-0 Ethilon on a BV-4 needle (Ethicon, Somerville, NJ) were used to make the vessel anastomoses. The mean carotid artery cross-clamp time was 25 minutes.

After hemostasis had been secured by gentle pressure, a solution of lidocaine hydrochloride was applied at the proximal and distal anastomoses to prevent spasm of the carotid artery. Patency was determined by direct inspection for arterial pulsation. After the operation on both carotid arteries, the wound was irrigated with saline solution and closed with 2-0 Dexon.

The rabbits were housed individually under controlled environmental conditions with free access to water and normal L.K.K. pellet rabbit food (Hope Farms BV, Woerden, the Netherlands). They did not receive any anticoagulants.

Graft Evaluation and Harvesting Procedure

The grafts were evaluated at 1 day ($n = 6$ rabbits), 1 week ($n = 6$), 2 weeks ($n = 6$), 3 weeks ($n = 8$), and 6 weeks ($n = 8$) after operation. The rabbits were then anesthetized with pentobarbital (Nembutal; 30 mg/kg body weight, administered intravenously). The composite vein grafts and control vein grafts were carefully dissected free, and heparin sodium (1,000 IU, intravenously) was given to prevent clotting caused by the harvesting procedure. All grafts were gently perfused with 6.8% sucrose solution in 0.1 mol/L cacodylate buffer and then fixed by pressure-controlled perfusion (100 mm Hg) with 2% glutaraldehyde in 0.1 mol/L cacodylate buffer.

Each of the fixed specimens was divided into two equal segments. Each segment was then prepared for and evaluated by routine light or scanning electron microscopy. Both forms of microscopy were used for morpho-

logic evaluation of the endothelial lining. Light microscopy was used for morphologic evaluation of the graft walls, the subendothelial smooth muscle cell layers as well as the adventitia.

Preparation for Scanning Electron Microscopy

The grafts, fixed by pressure-controlled perfusion, were dissected and left in the same fixative for 24 hours at 4°C. Next, the specimens were rinsed for 30 minutes in 6.8% sucrose solution in 0.1 mol/L cacodylate buffer, pH 7.4, to remove excess glutaraldehyde and postfixed for 3 hours in 1% osmium tetroxide in 0.1 mol/L cacodylate buffer, pH 7.4, at 4°C. After dehydration in an ethanol series up to 100%, the specimens were dried to the critical point with liquid carbon dioxide. Then they were cut into two or three longitudinal segments and sputter coated with gold (15 nm). These segments were examined in an ISI-DS-130 scanning electron microscope operated at 7 to 10 kV.

Preparation for Light Microscopy

The specimens were dehydrated in alcohol. After immersion in Technovit 8100 (Kulzer GmbH, Wehrheim, Germany) overnight, they were embedded in 40 mL of Technovit 8100 (solution A) and in 1 mL of the hardener Technovit 8100 (solution B). After polymerization at room temperature, semithin (2 μ m) sections were routinely cut and stained with hematoxylin and eosin and elastin stain (Verhoeff's stain).

Results

Unimplanted Vein Grafts

Unimplanted external (control) and internal jugular vein grafts (as in the composite vein grafts) consisted of an endothelial layer, an incomplete internal elastic lamina, a media with one to two layers of smooth muscle cells, and an adventitia composed of collagen. Both media and adventitia contained thin elastic laminae.

Control Vein Grafts

On day 1, the control vein grafts were deendothelialized over approximately 80% of the graft surface. The thin smooth muscle cell layers were completely disrupted, and many polymorphonuclear cells (PMNs) had infiltrated into the edematous wall (Fig 1a). Fragments of thin elastic laminae were observed in the vein wall (Fig 1c).

At 1 week, reendothelialization had occurred over approximately 50% of the graft surface. Disruption of the vein wall and edema with many PMNs were still observed (Fig 2a).

At 2 weeks, all control vein grafts were completely reendothelialized. At this time, as well as at 3 weeks, irregularly oriented fibrocytes had partly replaced the areas of disruption with PMNs (Fig 3a). Elastic laminae were no longer seen (Fig 3c). At 6 weeks, all areas of inflammation in the control vein grafts were completely replaced by mature fibrous tissue with an irregular structure (Fig 4a).

Composite Vein Grafts

The composite vein grafts were also deendothelialized over approximately 80% of the graft surface on day 1.

Fig 1. Light micrographs of (a, c) a control vein graft and (b, d) a composite vein graft 1 day after implantation. (a) In the control vein graft, there is complete disruption of smooth muscle cell layers with infiltration of many polymorphonuclear cells into the edematous vein wall. (b) In the composite vein graft, most smooth muscle cell layers are preserved. The vein wall is edematous. (c) In the control vein graft, only fragments of elastic laminae are present. (d) Elastic laminae are preserved in the composite vein graft. (a and b, nematoxylin and eosin; c and d, elastin stain [Verhoeff's stain]; all, $\times 250$.) (E = elastic laminae; P = prosthesis; V = vein wall.)

Although partial disruption of the smooth muscle cell layers was observed, most of them were still preserved and were arranged longitudinally. The vein wall had an edematous appearance in the deep layers but showed significantly less PMN infiltration than the control vein

grafts (Fig 1b). The thin elastic laminae normally present in the vein wall were preserved (Fig 1d).

At 1 week, the composite vein grafts were reendothelialized over approximately 75% of their surface. The vein wall by then showed regular layers of longitudinally

Fig 2. Light micrographs of (a) a control vein graft and (b) a composite vein graft 1 week after implantation. (a) Note the disruption of the smooth muscle cell layers in the control vein graft. Polymorphonuclear cells (arrows) are abundant in the edematous vein wall. (b) In contrast, the composite vein graft shows regular layers of immature fibroblasts with only a few polymorphonuclear cells. (Hematoxylin and eosin; $\times 250$.) (P = prosthesis; V = vein wall.)

oriented, immature fibroblasts with few PMNs (Fig 2b). Edema had disappeared, and thin elastic laminae were present. The prosthesis was surrounded and infiltrated by many macrophages and multinuclear giant cells.

At 2 weeks, endothelial coverage was complete. The vein wall had regular layers of longitudinally oriented, immature fibroblasts with only a very few PMNs. Thin elastic laminae were still present in the vein wall. Many macrophages and multinuclear giant cells were observed in and around the prosthetic material.

At 3 weeks, the vein wall had a similar aspect, but no PMNs were present (Figs 3b, 3d). By then, the prosthesis had started to fragment. At 6 weeks, the vein wall had gradually arterialized; it had increased in thickness and consisted of eight to 12 layers of immature fibroblasts. Moreover, in some areas, these layers had a prevalence for circular orientation (Fig 4b). Thin elastic laminae were observed but were less pronounced. Fragmentation of the prosthesis had continued slowly, and many macrophages and multinuclear giant cells were present.

Comment

The present study demonstrates that a compliant, biodegradable prosthesis can indeed function as a protective scaffold for autologous vein grafts when implanted into the arterial circulation: the prosthesis prevents overstretching of vein grafts, preventing subsequent damage [21]. We observed the preservation of smooth muscle cell layers and elastic laminae and only a minor inflammatory

reaction with few PMNs in the vein wall after 1 day of implantation. Moreover, the slowly degrading prosthesis allowed regular and gradual arterialization of the vein wall. In contrast, the unsupported control vein graft wall was completely disrupted after 1 day of implantation and showed severe inflammatory reaction of PMNs and edema. The walls healed with the formation of mature fibrous tissue without elastic laminae, resulting in fibrosis of the vein wall at 6 weeks.

The early changes observed in our control vein grafts resemble the changes described in coronary artery vein grafts in humans. After implantation, a large degree of deendothelialization occurs, and the media shows disruption of smooth muscle cell layers with edema and leukocyte infiltration [4-6]. All these changes in the vein wall might originate from damage to the vein graft during preparation [7, 8] or implantation [9, 10] and from ischemia [5, 6] and overstretching by the higher arterial pressures [9, 11, 12]. Regeneration occurs with reendothelialization and progressive medial fibrosis [4-6], as was observed in our control vein grafts. Later changes include intimal hyperplasia and atherosclerosis [4, 5].

Although many growth factors and enzymes might be involved in this process, a key role in the pathogenesis of vein graft degeneration is attributed to platelet-derived growth factor. It can be released not only by platelets but also by endothelial cells, smooth muscle cells, and monocytes [22-24].

To date, little attention has been paid to the influence on vein graft degeneration of the inflammatory reaction of

Fig 3. Light micrographs of (a, c) a control vein graft and (b, d) a composite vein graft 3 weeks after implantation. (a) Note the irregular arrangement of fibrocytes in the control vein graft. (b) The composite vein graft shows regular proliferation of immature fibroblasts. (c) In the control vein graft, elastic laminae have completely disappeared. (d) In the composite vein graft, elastic laminae are present. (a and b, hematoxylin and eosin; c and d, elastin stain [Verhoeff's stain]; all, $\times 250$.) (P = prosthesis; V = vein wall.)

PMNs in the vein wall caused by the disruption of the smooth muscle cell layers after implantation. In our rabbit model, the severe inflammatory reaction with PMNs in the disrupted layers of the control vein grafts was especially striking and lasted for the first 3 weeks in contrast to

the composite vein grafts. These activated PMNs release several enzymes, including elastase and collagenase [25]. These enzymes lyse, among others, elastic laminae and collagen, further destroying the integrity of the vein graft matrix. These inflammatory processes lead to fibrosis, as

Fig 4. Light micrographs of (a) a control vein graft and (b) a composite vein graft 6 weeks after implantation. (a) Note the irregular orientation of fibrocytes in the control vein graft. (b) The vein wall of the composite vein graft has increased in thickness and shows several layers of circularly oriented, immature fibroblasts (*) underneath the regular, longitudinally oriented layers. (Hematoxylin and eosin; $\times 250$.) (P = prosthesis; V = vein wall.)

observed in our unsupported control vein grafts, and might therefore play an additional role in the development of degenerative changes in vein grafts.

In contrast, the composite vein grafts showed no complete disruption of the smooth muscle cell layers and only a minor inflammatory reaction on 1 day. Already after 1 week, the regular, longitudinally oriented layers of immature fibroblasts had regenerated, most likely from transformed preserved smooth muscle cell layers in the vein graft wall [4, 6]. This transformation into fibroblasts might be induced by ischemia resulting from the unavoidable interruption of vasa vasorum [6, 26]. The organized structure of the supported vein graft walls might be due to the preservation of its matrix function, as demonstrated by the preservation of elastic laminae. During the following weeks, the vein wall gradually increased in thickness by regular proliferation of fibroblasts, which in some areas had a prevalence for circular orientation. Elastic laminae were less pronounced at 6 weeks, probably because of elastase produced by macrophages [27] that were present in the chronic reaction against the prosthetic material. The fibroblasts remained immature and did not become mature, ie, fibrocytes, as in the unsupported vein grafts. Long-term studies are required to see if these immature fibroblasts will differentiate into myofibroblasts and myoblasts and will produce elastin, thus resulting in the formation of an arteriallike structure.

In conclusion, this study demonstrated that a compliant, biodegradable prosthesis can function as a protective scaffold for autologous vein grafts. The reduced damage is

especially expressed by a reduced infiltration of PMNs. Our rabbit model appeared to be very sensitive for evaluating damage to vein grafts, resulting in already great short-term consequences for the control vein grafts. Long-term studies are warranted to determine the ultimate role of the supporting prosthesis in terms of the function and biological behavior of autologous vein grafts implanted into the arterial system of rabbits.

This study has been supported by The Netherlands Technological Foundation STW No. 88, 1482.

Safe Pulmonary Preservation for 12 Hours With Low-Potassium–Dextran Solution

Stig Steen, MD, PhD, Trygve Sjöberg, PhD, Giorgio Massa, MD, Leif Ericsson, MD, and Lars Lindberg, MD

Departments of Cardiothoracic Surgery, Pulmonary Medicine, and Anesthesiology and Intensive Care, University Hospital of Lund, Lund, Sweden

The function of porcine left lung allografts was studied after perfusion with (150 mL/kg) and storage for 12 hours in a 4° to 6°C low-potassium–dextran solution (Perfadex; Kabi Pharmacia AB, Uppsala, Sweden). After a left lung transplantation, an artificial lung in the form of venoarterial extracorporeal membrane oxygenation was established. The artificial lung has a “biological” heparin-coated surface (Carmeda AB, Stockholm, Sweden), and there is no need for systemic anticoagulation. Immediately thereafter, pneumonectomy of the normal right lung was done. All the animals were weaned from the artificial lung within 1 hour after the pneumonectomy.

Six animals were followed up for 24 hours. They were in good condition throughout the 24-hour observation period with arterial oxygen tensions around 200 mm Hg (inspired oxygen fraction = 0.4) and arterial carbon dioxide tensions around 40 mm Hg. This study demonstrates a reliable method for continuous evaluation of the function of a transplanted lung immediately after transplantation and over the ensuing postoperative period. Safe 12-hour lung preservation can be obtained with the low-potassium–dextran solution Perfadex.

(*Ann Thorac Surg* 1993;55:434–40)

Numerous lung preservation studies have been carried out using many different models and techniques of assessment, but often with conflicting results [1, 2]. Simple cooling of the lung by immersion is satisfactory for up to 5.5 hours [3]. In the discussions during the Second International Seminar on Transplantation for End-Stage Lung Disease in Zürich, June 27 and 28, 1991, it became clear that most centers use modifications of Euro-Collins solution as the flush solution for clinical lung preservation. Euro-Collins solution has an intracellular electrolyte composition with a high content of potassium (115 mmol/L) and no colloids or other substances with high molecular weights.

It has been shown that Euro-Collins solution preserves lungs for up to 6 hours [4]. Fujimura and associates [5] have reported greatly prolonged lung preservation with an extracellular type of flush solution containing dextran. They did not objectively assess early lung function. This was done by Cooper's group [6], who showed significantly better immediate function of the lung preserved with a low-potassium–dextran solution compared with Euro-Collins solution. Their study demonstrates the difficulties in assessing a single transplanted lung if the contralateral normal lung is left in place. They point out that the failure to assess the function in the transplanted lung alone has contributed to the confusion regarding techniques for lung preservation over the past 20 years.

The most logical way to solve the problem of early assessment would be to do a double-lung transplantation

or a pneumonectomy of the normal nontransplanted lung immediately after the transplantation, thereby making the animal 100% dependent on the newly transplanted lung. However, such procedures are accompanied by a high operative mortality, especially if the function of the transplanted lung is less than perfect. Therefore, Cooper's group [6] introduced left and right pulmonary artery (PA) occlusion cuffs in a canine left lung allotransplant model. With this model, the right PA can be occluded, permitting measurements of blood gases and hemodynamic variables for short periods during which the whole right cardiac output goes through the transplanted lung. The drawback of such a model is that it can be used only for short periods, as prolonged total occlusion of the PA will destroy the lung [7]. In a porcine model, we [8] have shown that when about 25% of the cardiac output goes through the lungs at normothermia, the integrity of the lungs is disturbed, although their capacity to transfer oxygen and carbon dioxide is good.

The aim of the present study was to develop an adequate method for continuous evaluation of the function of a transplanted lung immediately after transplantation and during the postoperative period. “A lung preservation technique suitable for clinical transplantation must reliably provide excellent function immediately and over the ensuing postoperative period” [6]. The method presented here includes single-lung transplantation, establishment of an artificial lung, and immediately thereafter, pneumonectomy of the contralateral normal lung. To test the method, we used a low-potassium–dextran solution for 12-hour pulmonary preservation in left lung transplantation in pigs.

Material and Methods

Fifteen Swedish native-breed pigs with a mean weight of 40 kg (range, 38 to 43 kg) were used (7 donors, 7 recipients, and 1 pig having a sham operation). All the animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Donor Procedure

Anesthesia was induced with intramuscular administration of ketamine hydrochloride (Ketalar; Parke-Davis, Morris Plains, NJ), 30 mg/kg, and atropine sulfate, 1 mg. Sodium thiopental (Pentothal; Abbott Laboratories, North Chicago, IL), 5 to 8 mg/kg, was given intravenously before a tracheostomy (No. 7 tube) was done. Anesthesia and muscular relaxation were maintained with a continuous infusion of 40 mL/h of a mixture of 3 g of ketamine, 200 mg of pancuronium bromide (Pavulon; Organon Teknika, Bostel, the Netherlands), and 10 mg of midazolam hydrochloride (Dormicum; Roche, Basel, Switzerland) dissolved in 500 mL of 10% glucose. The animals were ventilated with a Siemens-Elema Servoventilator 900B. Air enriched with oxygen to an inspired oxygen fraction of 0.4, and fixed-volume ventilation of 8.5 L/min, 20 breaths/min, and a positive end-expiratory pressure of 5 cm H₂O was used.

A median sternotomy was performed. The incision was carried down into the abdomen, and the abdominal viscera were lifted away from the diaphragm to avoid compressing the lower lobes of the lungs. After systemic heparinization (500 U/kg), a 28F cannula 30 cm long was inserted into the PA. The infusion system consisted of a tube 240 cm long with an inner diameter of 11 mm connected to the 28F cannula in the PA. An arterial catheter was also inserted into the PA through a separate pursestring suture. This catheter was used for continuous monitoring of PA pressure by means of a transducer connected to a polygraph during perfusion of the lungs.

The left and right pleural spaces were entered. All parts of the lungs were carefully inspected, and the positive end-expiratory pressure was increased temporarily until all atelectasis was eliminated. A temperature probe was placed in the upper lobe of the right lung as far anteriorly as possible. A pursestring suture was placed in the left atrial appendage, and the free ends of the suture were pulled through a small tourniquet.

The superior and inferior caval veins and the ascending aorta were clamped. A small cut was made within the pursestring suture in the left atrial appendage. The PA was flushed with 6 L (150 mL/kg) of cold (4° to 6°C) Perfadex (Kabi Pharmacia AB) solution. Perfadex is commercially available. One thousand milliliters of Perfadex contains the following: dextran 40 (Kabi Pharmacia AB), 50 g; Na⁺, 138 mmol; K⁺, 6 mmol; Mg²⁺, 0.8 mmol; Cl⁻, 142 mmol; SO₄²⁻, 0.8 mmol; H₂PO₄⁻ + HPO₄²⁻, 0.8 mmol; glucose, 0.91 g; and hydrochloric acid and sodium hydroxide to pH 6 with sterile water in sufficient quantity. The mean perfusion pressure was adjusted to between 10

and 20 mm Hg by changing the level of the Perfadex container or by regulating the size of the hole in the left atrial appendage.

The duration of the flushing was 9 minutes in the first 2 donors. In the last 5 donors, the flow (by elevating the Perfadex container) and the size of the hole in the left atrial appendage were increased, and the flushing time was reduced to a mean of 3 minutes 13 seconds (range, 3.10 to 3.25 minutes). No topical cooling of the lungs was used. During the entire perfusion period, the lungs were fully ventilated as already described. After perfusion, the tracheal tube was disconnected from the ventilator, and the lungs were permitted to collapse.

The heart-lung block was carefully excised (10 minutes) and placed in a bowl containing Perfadex. With the heart-lung block floating in cold Perfadex, the left lung was carefully dissected from the block (20 minutes). A large atrial cuff was fashioned around the orifices of the left lung veins. The left main bronchus was divided near the carina and closed with a suture. The left lung was then placed in a glass container with cold (4° to 6°C) Perfadex, and was kept under the surface with a multiperforated perspex disc. A temperature probe was submerged in the container, which was placed in a refrigerator. During storage, the temperature was kept at 4°C and was recorded on a polygraph.

Recipient Procedure

On the following day, the recipient pig was sedated and anesthetized as described for the donor. The animal received 1.2 g of intramuscular benzylpenicillin procaine (Ilocillin; Ciba-Geigy, Basel, Switzerland). A tracheostomy was carried out and a No. 7 tracheal tube inserted. Two central venous catheters were introduced through the internal jugular vein. A catheter was placed in the aorta through the carotid artery. A Foley catheter was inserted into the urinary bladder through a suprapubic cystostomy.

A left thoracotomy through the sixth intercostal space was done and a left pneumonectomy performed, with care being taken to leave long stumps on the artery, veins, and bronchus. The left main bronchus was occluded near the carina with a Satinski vascular clamp. The bronchial anastomosis was performed first with a running suture of 4-0 Prolene (Ethicon, Somerville, NJ). A low dose of heparin sodium (100 U/kg) was then given. A gracile Satinski vascular clamp was placed intrapericardially across the lateral wall of the left atrium, incorporating the stumps of the three to four left pulmonary veins. Great care was taken to avoid occlusion of the coronary sinus or the venous return from the infracardiac lobe of the right lung.

An atrial cuff was then formed by an incision joining the superior and inferior pulmonary veins. The atrial anastomosis was performed with a running 5-0 Prolene everting suture. This suture was left untied. A vascular clamp was placed on the proximal PA, and the PA anastomosis was performed with a running suture of 5-0 Prolene, which was left untied as well. The Satinski clamp on the bronchus was removed and ventilation started. The PA clamp was taken off, and when blood filled up to the atrial

suture line, the clamp was removed from the left atrium. A catheter for the measurement of left atrial pressure was placed into the left atrium through the opening between the untied sutures, which were then tied.

A blood flow probe (14 mm) was placed around the left PA, and flow was continuously monitored on a Transonic flowmeter T201D (Transonic Systems Inc, Ithaca, NY). After some minutes of ventilation with a temporary increase in positive end-expiratory pressure from 5 to 10 cm H₂O, all atelectases disappeared. When blood flow through the transplanted lung reached a steady level, the PA suture was tied without stenosis. The thoracotomy was closed with the help of towel clips.

The artificial lung was then prepared [7, 8]. It consists of a nonocclusive roller pump (Stöckert Instrumente, Munich, Germany), a hypothermia machine (Gambro, Lund, Sweden), and a hollow-fiber membrane oxygenator (Maxima; Medtronic, Anaheim, CA) with its built-in heat exchanger. A collapsible balloon placed in a sensor (Carmeda AB, Stockholm, Sweden) is interposed in the venous line. In the event of decreased venous return, this unit controls the roller pump. All surfaces that come in contact with the blood are supplied with a Carmeda Bioactive Surface (Carmeda AB) [9]. The artificial lung was primed with 5% human albumin (980 mL).

A sternotomy was performed. The pericardium was opened over the right atrial appendage, and a 5-0 Prolene pursestring suture was placed in the appendage. The right iliac artery was cannulated with a 20F wire-reinforced cannula (Research Medical Inc, Midvale, UT), and venous return to the artificial lung was provided by inserting a 28F wire-reinforced cannula into the right atrium; both these cannulas had been supplied with the Carmeda Bioactive Surface.

Bypass was initiated without administration of systemic heparin (apart from the 100 U/kg given in connection with the left atrial suture). A blood to oxygen gas ratio of 1:1 was held in the membrane oxygenator. The pig was turned with the right thorax up, and a right anterior thoracotomy was performed through the eighth intercostal space, connecting this incision with the abdominal part of the sternotomy. In this way, the right part of the sternum together with the cranial part of the thoracic wall could be lifted away, providing very good access to the right lung. Pneumonectomy of the right lung was done. In the last 2 pigs, the pneumonectomy was greatly facilitated by using a TA 90 long stapler (United States Surgical Corp, Norwalk, CT).

The pig was then placed in a semilateral position with the left side (ie, the transplanted lung) up. The right external jugular vein was prepared, and a No. 7 Swan-Ganz catheter was placed in the PA. Tracheal suction was carried out, and the transplanted left lung was inspected to ascertain that no atelectasis was present (a temporary increase in positive end-expiratory pressure to 15 cm H₂O was used to eliminate all atelectasis). From this point to the end of the experiment, the ventilator was fixed on a minute volume of 8.5 L with 20 breaths/min and 5 cm H₂O of positive end-expiratory pressure. From this moment, flow through the artificial lung was decreased gradually,

with particular attention paid to the central hemodynamics.

The fluid supply during the 24-hour experimental period was kept constant for all the animals and consisted of 960 mL of 10% glucose (ie, the anesthetic infusion of 40 mL/h), the 980 mL of 5% human albumin used as a priming solution (ie, after the artificial lung had been taken away, the blood in the circuit was given back), and 500 mL of 5% human albumin given as a continuous infusion during the last 12 hours of the experiment. No drugs were given during the experiment (except the anesthetics).

When blood flow had been established through the transplanted lung, the time was defined as zero. Blood gases (ABL 30; Radiometer, Copenhagen, Denmark) and oxygen saturation (OSM 3, adjusted for the pig mode; Radiometer), hemodynamics (all blood pressures were continuously displayed on monitors: Hewlett-Packard models HP78353B and HP78342B), lung compliance, urine volume, hemoglobin level, and hematocrit were registered every 4 hours throughout the experiment.

In the last pig in the study, a sham operation was done. A left thoracotomy and dissection of the left PA were carried out, and the flow probe was placed in the same position as if the lung had been transplanted. Everything else was performed in the same way as the recipient operations except that no artificial lung was used in connection with the right pneumonectomy.

Results

The mean ischemic time for the transplanted lungs was 12.75 hours (range, 12.5 to 13.5 hours). A typical polygraph registration of the donor procedure is shown in Figure 1. The lung temperature decreased to about 10°C (range, 8° to 14°C). Within 2 minutes after the end of perfusion, before the heart-lung block had been excised, the lung temperature increased to about 20°C and stayed there during the dissection (no topical cooling was used).

The mean time for the use of the venoarterial extracorporeal membrane oxygenator (ECMO) was 2 hours 20 minutes (range, 2 to 3 hours). A blood flow through the ECMO of up to 4 L/min could easily be obtained, but only 1.5 to 2 L/min was necessary to keep the central hemodynamics within normal limits during the right pneumonectomy. All the animals were weaned from the ECMO without difficulty within 1 hour after the right pneumonectomy had been done.

In pig 6, no urine production was seen although the central hemodynamics were within acceptable limits; acidosis was present (base excess, -12), and the oxygen saturation of mixed venous blood was very low (16%). The arterial blood gas measurements at 8 hours were as follows: oxygen tension, 92 mm Hg; carbon dioxide tension, 50 mm Hg; and oxygen saturation, 99%. There was still no urine production, and the experiment was terminated.

Minor variations were seen in blood gases and oxygen saturation throughout the 24 hours after transplantation (Fig 2). The compliance of the transplanted lungs was

Fig 1. Typical polygraph registration of the donor procedure showing pulmonary artery pressure (thin line) and temperature in the anterior segment of the superior lobe of the right lung (thick line). Ventilation with 20 breaths/min causes the fluctuations in the pulmonary artery pressure curve. (a = room temperature; b = temperature of Perfadex solution; c = lung temperature; d = clamping of caval veins; e = start of perfusion with 6 L of Perfadex solution; f = end of perfusion; g = lung temperature 45 seconds after perfusion.)

reduced after 4 hours of reperfusion but did not decrease further during the next 20 hours (Fig 3). The cardiac output, blood pressures, and urinary output were stable throughout the observation time (Fig 4) with only minor variations in systemic and pulmonary vascular resistances (Fig 5). The blood was diluted by the priming solution in the ECMO system to a hematocrit of 0.25 to 0.30 (Fig 6). There was no need for blood transfusions, diuretics, or other drugs.

The results obtained in the pig having a sham operation are shown in the figures as triangles connected by a broken line. Because no ECMO was used in this pig, it was not hemodiluted by the priming solution and its hematocrit was higher (see Fig 6). Moreover, as it did not get the priming solution of 980 mL of 5% albumin, its blood volume was less and its vascular resistance, greater (see Fig 5).

Comment

The use of venoarterial extracorporeal membrane oxygenation during the pneumonectomy of the contralateral normal lung made the operation safe without negative incidents of any kind. The ECMO system gives the opportunity to measure the function of the transplanted lung immediately and decide when it is possible to divert all venous return through the lung. With the knowledge of the blood flow through the ECMO system (ie, read from the calibrated roller-pump flow meter), cardiac output of the pig (ie, the flow through the transplanted lung), blood gases, oxygen saturation, and hemoglobin before and after passage through the artificial or transplanted lung, calculations of the oxygen delivery can be done and monitored continuously. The consequence of different perfusion pressures or flows in the transplanted lung can be investigated by regulating the flow through the artificial lung. If the transplanted lung has impaired function at the beginning, the time of extracorporeal membrane oxygenation can be prolonged as long as needed, as no anticoagulation is required and no major destruction of the blood occurs in healthy pigs. Our experimental and clinical experience with this novel artificial lung with the

"biological" Carmeda surface has recently been published [7, 8, 10-13]. Because all the transplanted lungs in this study had excellent early function, all the animals could be weaned from the ECMO after the pneumonectomy of the contralateral lung.

One animal in this study (pig 6) did not complete the whole observation period of 24 hours. No urine production was seen during the first 8 hours of observation. Transplantation, establishment of extracorporeal membrane oxygenation, and weaning from the artificial lung were performed without problems; the arterial blood gases and oxygen saturation were within acceptable limits. Therefore it is not probable that the anuria was caused by poor pulmonary preservation. The metabolic acidosis and the low mixed venous oxygen saturation measured in the pig suggest inadequate peripheral circulation as the cause of the anuria, although the hemoglobin level, aortic pressure, and cardiac output were not especially low. The study protocol did not allow any diuretics or other drugs to be given, and therefore that experiment was terminated.

A low-potassium-dextran solution has been shown to give better immediate lung function than Euro-Collins solution [6]. We [14] have shown that the high potassium content in Euro-Collins solution leads to strong pulmonary vasoconstriction, which is not significantly altered by prostaglandin E_1 . However, if the temperature in the PA is lower than 10°C, high potassium concentrations do not induce vasoconstriction [14]. A solution with no potassium or a low (ie, extracellular) concentration of potassium has an advantage over a high-potassium solution in that no vasoconstriction is induced. Vasoconstriction may cause impaired perfusion through more or less vasoconstricted regions of the lung. This situation creates a risk of underperfused or nonperfused regions with possible poor lung function after prolonged (ie, longer than 6 hours) storage.

What is thought to be the rationale for using a high potassium concentration in solutions for organ preservation? The basic hypothesis of Collins and Halasz [15] was that cation exchange across the cell membrane might be detrimental and can be avoided by flushing the organ

Fig 2. Function of transplanted left lung during the first 24 hours of reperfusion. Inspired oxygen fraction was 0.4. Arterial oxygen saturation (SaO₂), arterial oxygen tension (PaO₂), arterial carbon dioxide tension (PaCO₂), pH in arterial blood (pHa), and oxygen tension in mixed venous blood (PvO₂) from the pulmonary artery are shown as the mean $\pm$ the standard error of the mean (circles with uninterrupted line) ($n = 6$). The data for the pig having a sham operation are also shown (triangles with interrupted line).

with "intracellular" perfusate before anoxic hypothermic storage. This might save high-energy phosphate levels by decreasing the load on the sodium pump. To our knowledge, no studies have been published that demonstrate the advantages of high-potassium solutions in lung preservation.

More recently, attention has been focused on the content of cell membrane-impermeable solutes in organ preservation solutions. The maintenance of normal cell volume is an energy-requiring process and depends on the action of the cell membrane-bound Na-K adenosine triphosphatase. Sodium ions are actively pumped out of

Fig 3. Lung compliance (closed chest) of the transplanted left lung during the first 24 hours of reperfusion. Lung compliance was defined as $V_T/P_{\text{pause}} - PEEP$, where V_T = tidal volume, P_{pause} = airway pressure at the end of inspiratory pause, and PEEP = positive end-expiratory pressure. Data are shown as the mean $\pm$ the standard error of the mean (circles with uninterrupted line) ($n = 6$). The data for the pig having a sham operation are also shown (triangles with interrupted line).

the cell, and this creates an osmotic effect, balancing that of the cell membrane-impermeable intracellular anions, mainly proteins [16]. Ischemia, which is a consequence of most organ preservation methods commonly in use, will create a lack of adenosine triphosphate, which is needed

to give energy to the sodium pump. When the efficiency of this pump is reduced, sodium ions and water enter the cell and cause swelling of the cell and its organelles [17, 18]. Hypothermia, which is the mainstay of most organ preservation methods, inhibits Na-K adenosine triphosphatase, and the sodium pump becomes ineffective. Then cell swelling will occur even if sufficient levels of adenosine triphosphate are present [19]. It has also been shown that a difference in the cold sensitivity of the membrane pumps exists between different tissues; for example, the hypothermia-induced cell swelling is more prominent in the heart and liver than in the kidney [20].

The potential advantage of the addition of dextran to organ preservation solutions is that it is impermeable to cell membranes and therefore counteracts the obligatory

cell swelling caused by anoxic hypothermic storage. Glucose is an important solute in Collins solution. It has been shown to be relatively impermeable to kidney cell membranes; an adequate concentration of glucose will therefore balance the osmotic pressure of the kidney cell during ischemia/hypothermia, thus counteracting the cell swelling. This, rather than the high potassium content, is probably the explanation for the success of Collins solution in kidney preservation [21-24]. Collins solution is not able to counteract cell swelling in liver preservation because glucose is not impermeable to liver cell membranes; when solutes impermeable to liver cell membranes were added to liver preservation solutions, a breakthrough was obtained and safe preservation of the liver for 24 to 48 hours could be demonstrated [25]. To decide the adequate concentration of dextran in preservation solutions, further studies need to be done; the lower the temperature or the more cold sensitive the membrane pump in the particular organ, the higher the concentration of cell membrane-impermeable solute (eg, dextran) required to counteract the cell swelling.

Regardless of the type of organ preservation solution, an absolute prerequisite for successful long-term preservation of the lung is that the solution in question reaches all cells of the lung. We have observed that atelectatic parts of a lung will not be adequately perfused. It is therefore of the utmost importance that all parts of the lung be inspected before starting perfusion; if atelectasis is present, the ventilation must be increased temporarily until no signs of atelectasis can be seen. During perfusion, there must be enough ventilation to completely counteract the occurrence of atelectasis. We do not think that topical cooling during perfusion is essential; on the contrary, it might be harmful if its performance results in atelectasis.

Furthermore, deep hypothermia causes rigidity in the cell membranes [26], which will make them more vulnerable during dissection. In the present study, no topical cooling was used. The temperature in the lung during perfusion fell to about 10°C. Within 1 minute after completion of perfusion, the temperature became stable at around 20°C. The left lung was dissected ready for implantation at that temperature and then submerged in the 4°C low-potassium-dextran solution in an atelectatic state. Within 45 minutes, the temperature was 4°C in all lung regions (measurements done in the right lung).

We think it is essential that the perfusion pressure is adequate, ie, so high that it overcomes gravity and reaches the most anterior parts of the lung. In this study, the mean PA pressure was kept between 10 and 20 mm Hg during perfusion, and this effectively decreased the temperature in the most anterior parts of the lung, suggesting that these parts were perfused. If the hole made in the left atrial appendage is too large, the perfusion pressure can easily be too low unless the capacity of the infusion system used to deliver the preservation solution into the PA is high. The surgeon who is to harvest the heart most probably wants a large hole in the left atrium to decompress the heart fully. In an adult, high-flow perfusion will be needed to reach an adequate

Fig 6. Hemoglobin and hematocrit during the first 24 hours of reperfusion. Data are shown as the mean $\pm$ the standard error of the mean (circles with uninterrupted line) ($n = 6$). The data for the pig having a sham operation are also shown (triangles with interrupted line).

perfusion pressure for all parts of the lung. Most commercial infusion systems we have seen do not have that high-flow capacity.

In conclusion, this study presents a reliable method to examine the function in newly transplanted lungs. The low-potassium-dextran solution Perfadex provides good preservation of lungs for 12 hours.

This study has been supported by grants from the Svenska Nationalföreningen mot Hjärt-och Lungsjukdomar, Crafoordska Stiftelsen, T. Westerströms Stiftelse, and the Medical Faculty, University of Lund.

We thank Ms Siv Nilsson for assistance with the artificial lung.

Early Cardiac Allograft Rejection Is Independent of Regional Myocardial Blood Flow

John S. Pirolo, MD, Michael J. Liptay, MD, Elizabeth M. Brunt, MD,
Todd A. Shuman, MD, James L. Cox, MD, and T. Bruce Ferguson, Jr, MD

Division of Cardiothoracic Surgery, Department of Surgery, and Department of Pathology, Barnes Hospital, Washington University School of Medicine, St. Louis, Missouri

Noninvasive telemetric monitoring of canine heterotopic cardiac allograft unipolar peak-to-peak amplitude (UPPA) has permitted prospective surveillance for rejection; moreover, this technique is able to reliably detect rejection before the development of histologic evidence of myocyte necrosis. This study was performed to determine whether early cardiac allograft rejection and the accompanying decline in allograft UPPA were associated with alterations in regional myocardial blood flow (RMBF). Seven heterotopic, intrathoracic canine cardiac transplantations were performed using triple-drug immunosuppression. Native hearts and allografts were instrumented with right ventricular and left ventricular epicardial screw-in electrodes connected to subcutaneous telemeters. Daily measurement of native and graft UPPA was performed; using radioactive microspheres, native and graft RMBF were determined during the control period and when UPPA had declined by 15%, 30%, and 45%. Graft histologic status was determined by endomyo-

cardial biopsy at the time of RMBF determination. Mean duration of the study was 19.7 ± 3.9 days. Rejection was documented in all animals. The UPPA was stable in native hearts; UPPA declined in the allografts after the onset of rejection. A biphasic change in allograft blood flow was seen. Initially RMBF increased as UPPA declined; a 30% to 45% reduction in UPPA was associated with a 41% increase in RMBF ($p = 0.028$ versus allograft control). Subsequently, a significant decline in blood flow was observed for reductions in UPPA greater than 45% (0.68 ± 0.44 versus $1.07 \pm 0.47 \text{ mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$ for a 30% to 45% decline in UPPA; $p = 0.007$). The results of this study indicate that the initial stage of cardiac allograft rejection is not associated with a decline in RMBF. Moreover, the fall in UPPA that occurs with early rejection must be due to electrophysiologic factors that are independent of RMBF.

(*Ann Thorac Surg* 1993;55:441-9)

The peak-to-peak amplitude of the unipolar intramyocardial electrogram (UPPA) has been shown to be sensitive to a variety of alterations in myocardial physiology. The UPPA falls rapidly after the onset of acute regional ischemia in canine ventricular myocardium [1], and acute changes in ventricular volume have been shown to result in inverse changes in UPPA [2, 3]. In both animals and humans a decline in UPPA occurs during rejection in cardiac allografts [4-7]. This decline coincides with the development of mild histologic rejection and progresses linearly with increasing severity of rejection [5, 6]. The relationship between the degree of UPPA decline and the severity of rejection is unaffected by the presence of maintenance immunosuppression [6]. In addition UPPA has been shown to remain stable in histologically quiescent myocardium both acutely [6, 8] and chronically [8]. All of these characteristics suggest that the decline in UPPA is a specific electrophysiologic response to the cellular or humoral events occurring during cardiac allograft rejection. However, the mechanism of UPPA decline during acute allograft rejection is unknown.

One of the earliest histologic changes that occurs during rejection is a mononuclear perivascular infiltrate [9], and it has been suggested that alterations in regional myocardial blood flow (RMBF) may accompany the rejection process. The left ventricular (LV) RMBF in orthotopic cardiac allografts has been shown to decline during severe unmodified rejection [10-12]. However, the changes in RMBF during early rejection in the presence of cyclosporin A (CSA)-based immunosuppression are unknown. The present study was performed to determine if the initial rejection that occurs through CSA-based immunosuppression, and is accompanied by a decline in UPPA, is associated with alterations in RMBF.

Material and Methods

Experimental Preparation

Intrathoracic heterotopic cardiac transplantation was carried out as previously described [6]; briefly, donor hearts were obtained after cardioplegic arrest and implanted into the left chest of recipient animals with aorta-to-brachiocephalic and pulmonary artery-to-superior vena cava anastomoses. Before implantation a graft atrial septal defect was created by blunt disruption of the fossa ovalis.

Accepted for publication May 28, 1992.

During graft preparation, two unipolar epicardial electrodes were placed in midwall positions on the right ventricle and left ventricle of the native heart (Pacesetter Systems, Inc, Sylmar, CA), and an indwelling left atrial catheter was placed in the native heart for use in RMBF determinations. After implantation, the graft was deaired, reperfused, and cardioverted to normal sinus rhythm. After a 20- to 30-minute recovery period, two unipolar intramyocardial screw-in electrodes were placed in mid-wall positions on the allograft right and left ventricles (Pacesetter Systems, Inc). Care was taken to ensure that no evidence of regional hypoperfusion was present after electrode placement. The native heart electrodes and graft electrodes were connected to separate subcutaneously implanted telemetric pacemakers. Finally, a radiopaque tape was placed around the graft pulmonary artery near the anastomosis, the native left atrial catheter was positioned subcutaneously beneath the dorsal soft tissue, and the thoracotomy was closed. All animals were allowed to recover undisturbed for 5 days. Animals received humane care in compliance with the principles of laboratory animal care formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Immunosuppression Protocol

Recipients were given CSA (15 mg/kg) and methylprednisolone (500 mg intravenous bolus) preoperatively. Postoperatively, maintenance immunosuppression consisted of CSA (15 mg · kg⁻¹ · day⁻¹), prednisone (10 mg/day) and azathioprine (1.5 mg · kg⁻¹ · day⁻¹). If no evidence of rejection was present by postoperative day 18, azathioprine administration was discontinued and the daily CSA and prednisone dose was reduced by 50%.

Data Acquisition and Analysis

ELECTROGRAMS. Unipolar electrograms from each intramyocardial electrode were obtained by noninvasive telemetry (AFP Pulse Generator/Telemeter model 825; Pacesetter Systems Inc). The telemetered analog FM signal was acquired by a modified APS I programmer (model 370; Pacesetter Systems Inc [5]), digitized at 1,000 Hz, and subsequently displayed in real time (25 mm/s). Beginning on postoperative day 6, electrograms were recorded during sinus rhythm daily from each lead. All interrogations were performed with the animal awake and resting quietly. No attempt was made to schedule the acquisition of electrophysiologic data with respect to time of day.

The UPPA (in millivolts) was measured for all electrograms recorded during each interrogation, and a mean UPPA value was calculated for each lead. For both native hearts and allografts the daily UPPA was calculated as the sum of the mean UPPAs for the RV and LV electrodes. The control UPPA for both the native heart and allograft was then calculated as the respective mean daily UPPA over postoperative days 6 through 10 (control period). The daily UPPA for both the native heart and allograft was then normalized as percentage of the respective

control UPPA. A normalized daily UPPA of less than 85% control was considered positive for rejection and was used as an indication for RMBF determination and endomyocardial biopsy (EMB). Further reductions in UPPA to less than 70% and less than 55% of control were indications for subsequent RMBF determinations and EMBs.

REGIONAL MYOCARDIAL BLOOD FLOW DETERMINATION. All RMBF determinations were performed after anesthetic induction and ventilation and before EMB. Determinations of RMBF were performed using radioactive microspheres (14 μm diameter; 10% dextran suspension; Medical Products Division, 3M, St. Paul, MN) tagged with one of the following isotopes: cerium 141, chromium 51, niobium 95, scandium 46, or strontium 85. Before each determination microspheres were thoroughly mixed and then rapidly injected through the left atrial line (≈8.7 × 10⁶ microspheres/injection). Reference blood samples were withdrawn from the femoral artery using a withdrawal pump (Harvard Apparatus, South Natick, NJ) at 7.5 mL/min, beginning 15 seconds before microsphere injection and continuing for 2 minutes after injection.

At sacrifice the excised native and grafted hearts were prepared for counting by removal of atrial, pulmonary arterial, aortic, and valvular tissue and stripping of large epicardial arteries and veins. The RV and LV myocardium were then divided into 60 (20 RV, 20 LV endocardial [ENDO], and 20 LV epicardial [EPI]) tissue samples. These samples were weighed and counted for radionuclide activity. Raw counts were obtained using a gamma well counter (Packard Auto-Gamma 5000, Packard Instrument Co, Meriden, CT) and then corrected for background, decay, and spillover (Compusphere, Packard Instrument Co) to obtain final activity (CTS_{corr}). Regional myocardial blood flow (mL · g⁻¹ · min⁻¹) was calculated as:

$$\text{RMBF} = \left(\frac{\text{Sample CTS}_{\text{corr}}}{\text{Reference blood sample CTS}_{\text{corr}}} \right) \cdot \left(\frac{7.5 \text{ mL/min}}{\text{Sample wt (g)}} \right)$$

ENDOMYOCARDIAL BIOPSIES. Endomyocardial biopsy specimens were obtained as previously described [5]. A minimum of six tissue fragments were obtained at each biopsy session. These samples were prepared for histologic grading by formalin fixation and hematoxylin and eosin staining. Biopsy specimens were evaluated for the adequacy of sampling and presence or absence of rejection by a single pathologist blinded to the study design. Qualitative histologic grading classified rejection in each biopsy as none, mild, moderate, or severe [9]. Mild rejection was characterized by perivascular (or focal interstitial) lymphocytic infiltrates. Moderate rejection involved more extensive interstitial inflammation without myocyte necrosis. The presence of marked interstitial inflammation and myocyte necrosis characterized severe rejection.

Although the degree of rejection may vary among the tissue fragments obtained in any given biopsy [9], a single qualitative grade of rejection is usually assigned. To

quantify rejection in a manner that would reflect the intermediate degrees of rejection in biopsy specimens containing tissue fragments with various degrees of rejection, the following methodology was developed: the tissue fragments in each specimen were divided into two samples, A and B, composed of n_A and n_B tissue fragments, respectively. A single qualitative grade was then given to each sample, with a corresponding numeric value, k , assigned to each grade (none = 0, mild = 1, moderate = 2, severe = 3). A rejection score (RS) was then calculated for each biopsy specimen as follows [5, 6]:

$$RS = \frac{[(k_A \cdot n_A) + (k_B \cdot n_B)]}{(n_A + n_B)}$$

Rejection was present by histologic criteria for any biopsy specimen with an RS greater than 0.66. In using this methodology biopsy specimens in which two thirds or more of the fragments were graded as showing mild rejection and any specimen with a sample graded as showing moderate or severe rejection would have a calculated RS greater than 0.66. After the final EMB (ie, that EMB directed by the reduction in UPPA to less than 55% control) animals were sacrificed by anesthetic overdose (pentothal, 10 mg/kg) and intravenous potassium chloride.

HEMODYNAMICS. In 6 of the 7 animals, hemodynamic data were acquired immediately before termination of the study. After the final RMBF determination and EMB, the graft was reexposed through the original left thoracotomy and carefully dissected from the surrounding adhesions. Once the graft was mobilized the RV and LV systolic and diastolic pressures were obtained by transduction of a fluid-filled catheter inserted through the apices of the graft. Simultaneous recipient femoral artery pressures were obtained. After pressure recording, a large stent (5 mm diameter, 4 cm length) was inserted into the LV apex and a timed blood collection performed.

STATISTICAL ANALYSIS. Statistical comparisons of rejection score were made using an analysis of variance program (ANOVA; SYSTAT, Evanston, IL). Analyses of RMBF were performed using a three-factor ANOVA (SAS Inc, Cary, NC). Analysis of residual error terms resulting from ANOVA performed using the absolute values of blood flow measured for each heart indicated that the error terms resulting from the analysis could not satisfy the required tests of independence and normal distribution. Accordingly, a logarithmic transformation was performed on the blood flow data, and subsequent application of ANOVA resulted in residuals that satisfied the testing criteria. The logarithmic transformation was performed because of the greater power, interpretability, and control of experimentwise error rate available with ANOVA as compared with that available with nonparametric techniques. Type III sums of squares were performed to check for significant interaction effects between the factors ORGAN (native or graft heart) and UPPA (the four UPPA ranges used to direct RMBF measurements), and SITE

Fig 1. Mean ($\pm$ standard deviation) daily unipolar peak-to-peak amplitude (UPPA) for the native hearts in the study group. The arrow indicates the last day of the control period (postoperative days 6 through 10). Only 1 animal survived more than 23 days postoperatively.

(the RV, LV EPI, or LV ENDO regions). Based on the results of these factor analyses, subsequent analyses of treatment means were performed. Where appropriate, the p values reported have been corrected using Bonferroni procedures. Hemodynamic comparisons were made using Student's t test. In all statistical analyses significance was assigned for p values less than 0.05. All data are expressed as mean $\pm$ standard deviation.

Results

Seven heterotopic transplantations were performed. The mean duration of the study was 19.7 ± 3.9 days. Rejection was documented (both electrophysiologically and histologically) in all animals; in 2 animals histologic rejection was documented during the control period, and in 3 other animals rejection occurred through full immunosuppression. In the remaining 2 animals rejection was documented only after immunosuppression was reduced by 50%. At postmortem examination there was evidence of significant regional inflammation, including the presence of pleural effusions in all animals and, in several cases, native heart pericardial effusions.

Unipolar Peak-to-Peak Amplitude

Figure 1 shows the mean daily UPPA telemetrically recorded from native hearts on each postoperative day for the group. Analysis revealed a high degree of native heart UPPA stability over the 103 experimental days. In 101 of 103 determinations (98%) the normalized UPPA was greater than 85%. In 2 animals, the normalized UPPA was less than 85% on one occasion. One of these occurred during the control period (normalized UPPA = 82.4%) and one occurred immediately after the control period (normalized UPPA = 83.5%). None of these occurred after a reduction of immunosuppression. In 1 animal (normalized UPPA = 83.5%) the reduction in UPPA occurred in the presence of mild to moderate rejection in the graft. However, in that animal UPPA returned to levels greater than 85% control on the following day and remained

above that level even in the presence of subsequent severe graft rejection.

Seven baseline EMBs were performed (one in each animal); six of these were negative for rejection. In 1 animal the initial control biopsy specimen was associated with mild rejection (normalized UPPA = 96.5%; RS = 1.0). After the control period 20 UPPA-directed EMBs were performed; three of 20 were prompted by persistent UPPA stability (normalized UPPA $\geq$ 85%) during postoperative days 11 through 16, and 17 of 20 were due to a reduction in UPPA to less than 85% (6 EMBs; mean RS = 1.38 ± 0.80), less than 70% (5 EMBs; mean RS = 1.96 ± 0.35), or less than 55% (6 EMBs; mean RS = 2.41 ± 0.82) control. In specimens from one of the three biopsies directed by UPPA stability during the first week after control, mild rejection was noted (normalized UPPA = 92.7%; RS = 1.0). Among the 17 biopsies directed by a decline in UPPA, one showed no rejection (normalized UPPA = 80.5%; RS = 0) and 16 showed rejection. Successive declines in UPPA correlated with increasing severity of rejection ($p < 0.001$). Figure 2 shows the mean normalized UPPA and the mean RS calculated for each normalized UPPA range.

Regional Myocardial Blood Flow

Figure 3 shows the mean control and overall RMBF by organ and site. Type III sums of squares for the interactions of ORGAN and UPPA, SITE and UPPA, and ORGAN, SITE, and UPPA revealed no significant differences (p values = 0.483, 0.999, and 0.952, respectively). A significant difference was noted for ORGAN and SITE ($p = 0.017$). Accordingly, subsequent analyses of mean RMBF for various sites in both native and graft hearts were performed. Overall native RV RMBF was significantly lower than LV RMBF (0.76 ± 0.41 versus 1.36 ± 0.55 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$; $p = 0.001$). No difference was seen between native LV ENDO and EPI RMBF ($p = 0.356$). Native LV RMBF was significantly greater than the graft LV RMBF (1.36 ± 0.55 versus 0.82 ± 0.45 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$; $p = 0.001$). No difference was seen between native and graft RV RMBF (0.77 ± 0.41 versus 0.78 ± 0.51 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$; $p = 0.959$); however, RMBF was greater in native LV ENDO and EPI regions than in corresponding regions of the grafted hearts (1.45 ± 0.56 versus 0.89 ± 0.41 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$ for ENDO and 1.28 ± 0.55 versus 0.79 ± 0.44 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$ for EPI; $p = 0.001$ for both comparisons). Within the grafted hearts no differences were seen between RV, LV ENDO, and LV EPI RMBF ($p = 0.315$ for RV versus LV total, and $p = 0.333$ for LV EPI versus LV ENDO).

Figure 4 shows the mean RMBF by organ, site, and normalized UPPA range. Analysis of variance revealed a significant difference in RMBF in both native and graft hearts when blood flow was referenced to graft UPPA level. Overall RMBF declined in native hearts as graft UPPA declined ($p = 0.001$); however, this difference emerged only after the graft UPPA had fallen to less than 55% ($p = 0.005$). No decline in native RMBF was associated with the observed decline in native RMBF. Native RV, LV ENDO, and LV EPI RMBF when graft UPPA was

B

Fig 2. (A) The mean normalized unipolar peak-to-peak amplitude (UPPA) for each range of UPPA values (U) that determined the timing of regional myocardial blood flow determinations and endomyocardial biopsies. Normalized UPPA less than 85% was considered indicative of rejection. (B) Mean rejection score calculated for endomyocardial biopsy specimens obtained for each range of normalized UPPA values. A calculated rejection score of 0.66 or greater was considered positive for rejection.

less than 55% were 0.45 ± 0.16 , 1.07 ± 0.35 , and 0.83 ± 0.25 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$, respectively. No change in native RMBF was noted for reductions in normalized graft UPPA of 15% to 30% or 30% to 45% ($p > 0.631$).

In contrast, a biphasic relationship between graft RMBF and normalized graft UPPA was noted. Initially an upward trend in overall RMBF with decreasing UPPA was seen, which became significant for a 30% to 45% decline in UPPA (1.07 ± 0.47 versus 0.76 ± 0.37 mL $\cdot$ g $^{-1}$ $\cdot$ min $^{-1}$ [control value]; $p = 0.028$). After this increase a significant reduction in RMBF occurred with the further decline in normalized graft UPPA to less than 55% (0.68 ± 0.44

Fig 3. Mean control (A) and overall (B) regional myocardial blood flow (RMBF) for the native hearts and allografts by ventricular site. See text for specific statistical comparisons. (ENDO = endocardium; EPI = epicardium; LV = left ventricular; RV = right ventricle.)

versus $1.07 \pm 0.47 \text{ mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$; $p = 0.007$). No difference was seen between overall graft RMBF for normalized graft UPPA less than 55% and graft RMBF during control periods (0.68 ± 0.44 versus $0.77 \pm 0.37 \text{ mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$; $p = 0.074$). The biphasic relationship between graft RMBF and normalized graft UPPA was seen for all sites (RV, LV EPI, and LV ENDO) within the grafted hearts.

Allograft Hemodynamics

Figure 5 summarizes the hemodynamic data obtained for the 6 animals studied immediately before sacrifice. It should be noted that all of these measurements were obtained after a decline in UPPA to less than 55% control (during moderate to severe rejection; $RS = 2.41 \pm 0.82$). Mean RV systolic/diastolic pressures for the group were $18.0 \pm 5.3/4.0 \pm 2.5 \text{ mm Hg}$. Mean LV systolic/diastolic pressures for the group were $118.2 \pm 47.5/12.0 \pm 8.9 \text{ mm Hg}$. It is of note that in 4 of 6 dogs the maximal LV systolic pressure was less than or equal to the recipient femoral artery diastolic pressure (maximal pressure gradients be-

tween the graft LV and the recipient femoral artery for the remaining 2 animals were 27 and 70 mm Hg). Blood flow into the graft LV cavity varied widely (20 to 200 mL/min). The mean LV cavity flow was $74.8 \pm 52.3 \text{ mL/min}$.

Comment

This study was designed to examine the relationship between UPPA and cardiac allograft RMBF. Although previous hemodynamic studies have demonstrated a decline in LV RMBF during acute rejection occurring in a setting of non-cyclosporine-based immunosuppression [10-12], those studies did not examine the relationship between the early phases of allograft rejection and RMBF under the influence of CSA. Furthermore, those studies used an orthotopic model of cardiac transplantation that, although comparable with the clinical transplant situation, is complicated by wide variability of myocardial energy demands that could obscure underlying rejection-mediated changes in RMBF. In addition, the time course of this decline in RMBF was unclear; RMBF was shown to

Fig 4. Mean regional myocardial blood flow (RMBF) for the native hearts and allografts by organ, ventricular site, and normalized unipolar peak-to-peak amplitude (UPPA) range. See text for specific statistical comparisons. (ENDO = endocardium; EPI = epicardium; LV = left ventricular; RV = right ventricle.)

Fig 5. Summary of mean pressure data obtained at the time of terminal hemodynamic study (normalized allograft unipolar peak-to-peak amplitude < 55%). (BP, GLV, and GRV = recipient femoral artery, allograft left ventricular, and allograft right ventricular pressures, respectively; DIAS and SYS = diastolic and systolic pressures, respectively.)

decline as early as 2 to 3 days after transplantation in some studies [10]; however, other studies found no changes in LV RMBF during early rejection, with a decline in RMBF only after the development of marked rejection 8 to 10 days after transplantation [11, 12]. Finally, extrapolation of previous assessments of allograft RMBF to the current clinical setting of cardiac transplantation is difficult, as these previous studies did not use CSA-based immunosuppression, which has been demonstrated to alter the histologic character of rejection [13]. In this study we have measured native and allograft RMBF at times dictated by the telemetrically acquired UPPA data; it has been previously shown that this technique can be used in a prospective manner to accurately monitor cardiac allografts for the onset of rejection in this model [6]. This methodology permitted comparison of histology and RMBF as determined by an independent predictor of the rejection process. This in turn allowed comparison of these two variables at an early stage of rejection that was consistent from animal to animal, a process that would not be possible if EMB and RMBF determinations had been performed on a fixed time schedule.

Endomyocardial Biopsy and Regional Myocardial Blood Flow

Under standard CSA-based immunosuppression the initial stages of histologic rejection, consisting of the development of a perivascular infiltrate without myocyte necrosis, occurred independently of a fall in RMBF. At a time when the rejection process led to a significant decline in UPPA in this study, RMBF was actually increased over the control allograft RMBF value. It should be noted that the average RS at the time of the initial first true-positive UPPA was 1.63 ± 0.45 on a scale of 0 to 4. This corresponds to an earlier stage of histologic rejection than would warrant treatment by conventional clinical practice at this time [6].

Unipolar Peak-to-Peak Amplitude and Regional Myocardial Blood Flow

The results of this study also indicate that a reduction in allograft RMBF does not accompany the decline in UPPA

occurring with mild to moderate rejection. Rather, the changes in RMBF that occur during sequential degrees of UPPA decline appear to be biphasic. We observed a small (17%) but not statistically significant increase in allograft RMBF with the initial 15% to 30% decline in UPPA that accompanied histologically mild rejection. A further decline in UPPA (to 30% to 45% of control values) corresponded to the progression of rejection (mild to moderate) and was associated with a significant increase (41%) in overall RMBF. Subsequently, the decline in UPPA associated with severe rejection (UPPA < 55% of control) occurred in conjunction with a reduction in overall RMBF. Although this decline was statistically significant with respect to the RMBF measured during lesser declines in UPPA, it amounted to only an approximately 11% reduction in RMBF from control flows (p = not significant versus control RMBF). This biphasic pattern may reflect the initial acute inflammation occurring during mild to moderate rejecting with subsequent vascular and parenchymal damage developing during severe rejection. These results are similar to those reported by Dumont and associates [12], who, in an orthotopic model, observed no change in allograft RMBF during early rejection but noted a significant decrease during severe rejection. It is of note that in that study there was no method of marking the development of intermediate changes in rejection (ie, the progression of mild to moderate) and thus there was no means of determining interval changes in RMBF.

Control RV, LV ENDO, and LV EPI RMBF measured in this group of native hearts were within the physiologic range of flows previously reported [10, 11]. No change in overall native RMBF was seen with 15% to 45% reductions in allograft UPPA. With greater than 55% declines in UPPA (severe allograft rejection) a 39% reduction in overall native RMBF was seen. Although the fall in RMBF was significant, the absolute native blood flow did not decline to physiologically ischemic levels for LV ENDO ($1.07 \text{ mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$) or LV EPI ($0.84 \text{ mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$) regions. A more marked decline was seen in the native RV regions ($0.44 \text{ mL} \cdot \text{g}^{-1} \cdot \text{min}^{-1}$; 51% reduction from control). That these reductions in flow did not result in significant native myocardial ischemia is supported by the absence of ischemic changes in UPPAs recorded from native hearts during severe allograft rejection. It is possible that the systemic effects of circulating immune or inflammatory mediators may influence the perfusion of other host organs such as the native heart, thus accounting for the fall in native RMBF.

Heterotopic Hemodynamics

In the heterotopic model employed in this study a low-pressure circuit is present on the right side with graft RV and LV preload determined by coronary flow and flow across the atrial septal defect, respectively. As noted in this study graft RV diastolic pressure ($\approx$ RV preload), even during periods of moderate to severe rejection, is relatively low. The combination of low graft RV preload and the fixed resistance of the atrial septal defect should result in a reduced and relatively constant graft LV preload. Low allograft LV preload in conjunction with dyssynchronous

Fig 6. Mean overall allograft regional myocardial blood flow (RMBF) during the course of study. To the extent that total RMBF represents coronary flow at any given time, the right ventricular preload during early rejection is unchanged. (UPPA = unipolar peak-to-peak amplitude.)

and relatively high afterload (recipient arterial pressure) may result in nonejecting (isovolumic) graft LV function. Analysis of the hemodynamic data obtained in this study supports this. The observed graft LV cavity/recipient femoral artery gradients suggest that, in the heterotopic position, the allograft LV may function largely as an isovolumic preparation. To a lesser extent the heterotopic allograft RV volume may also remain stable; in this preparation RV volume is determined by coronary flow, which remained relatively stable during the course of the study (Fig 6).

It has been shown that significant increases in cardiac tissue volume occur with the edema and cellular infiltration that accompany severe rejection [13], and acute increases in allograft ventricular volume (created with rapid volume infusion or as seen with RV outflow tract obstruction) have been shown to cause a fall in UPPA [6]. Thus myocardial wall or cavity volume changes could contribute to the observed decline in UPPA. Although volume changes may contribute to the marked declines in UPPA that occur in the presence of severe rejection, it is unlikely that volume changes can be invoked as the cause of the initial fall in UPPA because (1) the histology seen in early rejection is marked by minimal cellular infiltration or edema and (2) as discussed above, the heterotopic allograft cavity volumes may be relatively constant over time.

Limitations

The significance of RMBF changes with respect to the presence or absence of ischemia can be completely determined only in the context of myocardial energy demand. Although the hemodynamic data presented here suggest that a major consequence of heterotopic position may be a more constant energy demand than that present in orthotopically placed grafts, precise information regarding allograft heart rate during the various stages of rejection is not available, and hemodynamic assessments were not made during episodes of early rejection. Although it

seems reasonable that the changes in RMBF relate primarily to the sequelae of rejection rather than acute changes in work-related myocardial energy demands, we cannot exclude the possibility that significant increases in myocardial energy demand may be mediated directly by immune cells or circulating inflammatory mediators.

Conclusion

The early immune response during cardiac allograft rejection is focused on the myocardial microvasculature. The results of this study demonstrate that these histologic changes do not occur in association with reduction in absolute global or regional myocardial blood flow. Furthermore, the decline in UPPA that indicates the onset of early histologic rejection occurs despite the maintenance of global and regional blood flow. This suggests that the decline in UPPA is due to electrophysiologic factors that are not mediated by myocardial blood flow per se in this setting.

Plasma Endothelin Levels and Surgically Correctable Pulmonary Hypertension

Hang Chang, MD, Gong-Jhe Wu, MD, Shih-Ming Wang, MD, and Chi-Ren Hung, MD

Departments of Emergency Medicine and Surgery, National Taiwan University Hospital, Taipei, Taiwan, Republic of China

To know the changes in plasma endothelin of patients with pulmonary hypertension, we studied 32 patients with valvular heart disease. Among them, 22 patients had pulmonary hypertension (group I) and 10 had pulmonary arterial pressures in the normal range (group II). Plasma endothelin-1 concentrations of the patients in group I were significantly greater than those of the patients in group II ($p < 0.05$). No significant difference in plasma endothelin-3 concentrations existed between the two groups. Cardiac output and pulmonary capillary wedge pressure had a linear correlation with plasma endothelin-1 levels. There was also a significant correlation between plasma endothelin-1 levels and hemodynamic indicators of severity of pulmonary hypertension, such as mean pulmonary arterial pressure and pulmonary vascular resistance ($p < 0.05$). All patients in this

study underwent surgical procedures for the correction of valvular lesions. All patients in group I showed a decrease in pulmonary arterial pressures, and their plasma endothelin-1 levels decreased from 3.84 ± 0.20 pg/mL to 1.66 ± 0.07 pg/mL ($p < 0.05$), whereas the plasma endothelin-3 levels had only slight variation from 0.64 ± 0.11 pg/mL to 0.75 ± 0.06 pg/mL ($p > 0.05$) between the preoperative and the postoperative stages. The results demonstrated that plasma endothelin-1 rather than endothelin-3 had a role in pulmonary hypertension. Several pieces of evidence pointed out that endothelin-1 functioned as a reactive mediator during vasoconstriction in the case of pulmonary hypertension rather than as a triggering factor of pulmonary hypertension.

(*Ann Thorac Surg* 1993;55:450-8)

Pulmonary hypertension refers to the abnormal hemodynamic consequence of various conditions that lead to a chronic increase in the pulmonary arterial pressure. The pulmonary arterial pressure is related to the physiologic pulmonary arterial blood flow, the pulmonary venous pressure, and the pulmonary vascular resistance. Chemical and hormonal regulation of pulmonary vascular resistance is a complex and as yet incompletely understood subject. Catecholamine, acetylcholine, prostaglandin, histamine, bradykinin, serotonin, and angiotensin have been reported to play a role in the regulation of pulmonary vascular resistance [1, 2]. However, the exact site where these agents' regulating function occurs within the pulmonary vascular tree is still uncertain.

Furchgott and Zawadzki [3], in 1980, first reported that endothelial cells played a necessary role in determining response to a variety of vasoactive substances. Afterward, some authors have demonstrated the protease-sensitive contractile activity in the supernatants of cultured endothelial cells [4]. All of the above-mentioned experiments indicated that the vasoactive mediators released from endothelial cells played an important role in the regulation of vascular resistance. Hickey and associates [5], in 1985, revealed the existence of an endothelial cell-derived polypeptide with the characteristics of a vasoconstrictor. Yanagisawa and colleagues [6], in 1988, described a 21-amino acid polypeptide (endothelin) that had been suc-

cessfully isolated from cultured porcine endothelial cells. Further experiments [7] have also proved that intravenous administration of endothelin can exert a number of cardiovascular effects, including a sustained, dose-dependent increase in the mean arterial pressure and total peripheral resistance, and a decrease in cardiac output and heart rate. More recently, some authors have reported that endothelin-1 induces contractions in isolated pulmonary vessels and increases pulmonary vascular resistance [8], whereas other experiments have shown that endothelin-1 possesses a vasodilative function in systemic as well as pulmonary circulation [9].

The divergent views regarding the physiological function of endothelin in vascular resistance have been widely discussed. Kohn and associates [10] demonstrated increased plasma endothelin concentrations in patients with essential hypertension. They thought that an increase in the transmural pressure of vessels with the development of hypertension was responsible for the elevation of plasma endothelin levels. Because (1) the reaction to hypertension of endothelial cells in both pulmonary and systemic circulation is similar, (2) endothelin was rapidly processed out of big endothelin in the lungs, and the intensity of activities of processing enzymes was higher than in other tissue as revealed by Kitamura and colleagues [11], and (3) circulating endothelin is rapidly cleared primarily by the lungs as reported by de Nucci and co-workers [12], it has been suggested that the plasma endothelin level will increase when clearance rate decreases or secretion rate of pulmonary endothelial cells increases in some pathological conditions.

We do not know the relationship between plasma endothelin and pulmonary hypertension. Using surgical correction of valvular heart disease to lower the pulmonary arterial pressure and then comparing the changes of plasma endothelin level before and after operation, we attempted to elucidate the mechanism and physiological role of circulating endothelin in patients with pulmonary hypertension.

Material and Methods

From August 1990 to April 1991, 32 patients with valvular heart disease were studied at National Taiwan University Hospital. Patients' ages ranged from 15 to 70 years with a mean of 48 years. Sixteen patients were male and 16 female. According to the New York Heart Association classification, 10 patients (31%) were in class II, 17 (53%) in class III, and 5 (16%) in class IV. The cause of valvular lesion was recognized in all patients. Rheumatic valvular disease was the cause in 30 patients (94%). Two patients (6%) had degenerative valvular disease. Previous operations on the mitral valve, aortic valve, or both had been performed in 17 patients (53%) 4 to 12 years earlier (mean, 9.4 years). Among them, 15 patients had xenograft tissue valve failure due to calcification or tear of the valve cusp and 2 patients had recurrence of mitral stenosis or insufficiency after a previous reconstructive operation on the mitral valve.

The preoperative hemodynamic study was always carried out within 1 month of the operation. Catheterization of both sides of the heart was routinely performed in each patient to obtain the pressure data in the cardiac chambers and great vessels. Pulmonary arterial pressures consistently in excess of 35 mm Hg systolic, 15 mm Hg diastolic, and 25 mm Hg mean were regarded as indicative of pulmonary hypertension.

Surgical correction of the valvular lesion by way of cardiopulmonary bypass was performed in the usual manner. The postoperative hemodynamic status was evaluated on the fourth postoperative day with a Swan-Ganz catheter, which was inserted immediately after the initiation of anesthesia in the operating room before operation.

For comparison of plasma endothelin-1 and endothelin-3 levels between normal control subjects and the patients with pulmonary hypertension, 10 normal volunteers (average age, 24 years; range, 23 to 25 years) were invited to participate in this study; informed consent was obtained from all patients and volunteers. Central venous blood was collected with the volunteers resting in a supine position for 10 minutes before blood sampling. To observe the changes in plasma endothelin-1 and endothelin-3 levels of patients in this study, blood samples were taken in the same way at the time before operation (patient premedicated, after placement of central venous catheter, but before induction of anesthesia) and 3 months after operation.

The blood samples (10 mL) were put into a chilled syringe right after collection and then transferred into a polypropylene tube containing ethylenediaminetetraace-

tate (1 mg/mL) and aprotinin (500 KIU/mL; Trasylol, Leverkusen, Germany) at 4°C; the tubes were then centrifuged at 3,000 g for 20 minutes at 0°C. The plasma was collected and stored at -70°C until radioimmunoassay. There was no significant correlation between the duration of storage time and levels of endothelin immunoreactivity.

Extraction of Endothelin

Extraction of plasma endothelin was done by a modification of the method previously described [10]. Sep-Columns (Peninsula Laboratories, Inc, Belmont, CA) containing 200 mg of C₁₈ cartridge were activated by washing them with buffer A (60% acetonitrile in 0.1% trifluoroacetic acid; 4 × 1 mL) and then with buffer B (0.1% trifluoroacetic acid; 4 × 5 mL). Each plasma sample was acidified by adding an equal volume of buffer B and then centrifuged at 3,000 g for 15 minutes at 4°C. The mixture of plasma and buffer B was pumped at a rate of 1 mL/min into the activated Sep-Columns. After the Sep-Columns were washed with buffer B (4 × 5 mL), the absorbed endothelinlike materials were slowly eluted with buffer A (3 × 1 mL) into a polypropylene tube. The eluent was completely evaporated with a centrifugal evaporator (Savant Instruments, Inc, Farmingdale, NY). The recovery rate was calculated by adding three different quantities of cold endothelin-1 and endothelin-3 (2 pg/mL, 4 pg/mL, and 8 pg/mL) to plasma with dextran-coated charcoal. The recovery rate was 71% ± 2% for endothelin-1 and 67% ± 4% for endothelin-3.

Radioimmunoassay of Endothelin-1

The plasma endothelin-1 level was measured by using a radioimmunoassay kit for the detection of duplicate samples (endothelin-1; Peninsula Laboratories). The endothelin concentrations were determined by applying antibody to synthetic endothelin-1 and iodine 125-labeled endothelin-1. This antibody cross-reacted 100% with endothelin-1, 7% with endothelin-2, 7% with endothelin-3, and 17% with big endothelin (human). The antibody did not cross-react with α -human atrial natriuretic peptide, angiotensin I, II, and III, vasopressin, adrenocorticotrophic hormone, vasoactive intestinal polypeptide, and big endothelin 22-38 (human). Samples and standards (endothelin-1; Peninsula Laboratories) were dissolved in assay buffer and incubated for 24 hours with rabbit anti-endothelin-1 serum (Peninsula Laboratories) at 4°C. Approximately 12,000 cpm of iodine 125-labeled endothelin-1 was added to each tube and incubated for another 24 hours at 4°C. Diluted normal rabbit serum and goat anti-rabbit immunoglobulin G serum were added on the third day. The contents of each tube were vortex-mixed and incubated at room temperature for 120 minutes. After centrifugation at 1,700 g for 30 minutes, the supernatant was removed by aspiration, and the pellet was counted for iodine 125 with a gamma counter (Packard Cobra Auto-gamma, Canberra Company, Japan). The standard curve was defined by the

AR = aortic regurgitation; AS = aortic stenosis; BP = systemic blood pressure; CO = cardiac output; ET = endothelin; FC = functional class; MPAP = mean PAP; MR = mitral regurgitation; MS = mitral stenosis; MVP s/p = previous mitral valvuloplasty; OMC s/p = previous open mitral commissurotomy; NYHA = New York Heart Association; PAP = pulmonary arterial pressure; PCWP = pulmonary capillary wedge pressure; PVR = pulmonary vascular resistance; XGT = xenograft tissue valve failure.

equation: $\logit B/B_0 = 9.85193 - 0.101576 \log \text{pg endothelin-1}$ ($r^2 = 0.99$). The lower limit of detection was 1.0 pg/tube. The interassay variation was 8.4% and the intraassay variation was 6.8%.

Radioimmunoassay of Endothelin-3

The plasma endothelin-3 level was measured by using a radioimmunoassay kit (endothelin-3; Peninsula Laboratories) the same way as for plasma endothelin-1. The kit had an antibody that cross-reacted less than 2% with endothelin-1, 1% with endothelin-2, 0.001% with sarafotoxin S₆B, and 0.01% with brain natriuretic peptide 26 (porcine), and did not cross-react with angiotensin II, arginine-vasopressin, α -atrial natriuretic peptide (human), vasoactive intestinal polypeptide, and substance P. The standard curve was as follows: $\logit B/B_0 = 10.0485 - 0.103885 \log \text{pg endothelin-3}$ ($r^2 = 0.99$). The interassay and intraassay

variation were 8.6% and 6.3%, respectively. The lower limit of detection was 1.0 pg/tube.

Statistical Analysis

Group data are presented as mean $\pm$ standard error. For the comparison of endothelin values of the patients with and without pulmonary hypertension, one-way analysis of variance was performed. Paired *t* test was used to assess the change in plasma endothelin concentration from preoperative to postoperative stage. For the comparison of the associated significance between each event and plasma endothelin levels, linear regression analysis was used to check the effect of each variable on the elevation of endothelin level in plasma. Kruskal-Wallis analysis was used to study the relation of the plasma endothelin concentrations to the New York Heart Association func-

Results

The characteristics of the 32 patients in this study are shown in Tables 1 and 2. Twenty-two patients had pulmonary hypertension (group I), among whom the highest pulmonary arterial pressures were 96 mm Hg systolic, 48 mm Hg diastolic, and 64 mm Hg mean pulmonary arterial pressure. Their average systolic, diastolic, and mean pulmonary arterial pressures were 63 mm Hg, 28 mm Hg, and 41 mm Hg, respectively. The mean pulmonary capillary wedge pressure was 26 mm Hg for the 22 patients in group I, with the highest pressure being 38 mm Hg. Ten patients with valvular heart disease had pulmonary arterial pressure within normal limits (group

II). The average systolic, diastolic, and mean pulmonary arterial pressure and the pulmonary capillary wedge pressure recorded in group II were 28 mm Hg, 12 mm Hg, 18 mm Hg, and 14 mm Hg, respectively.

The preoperative plasma endothelin-1 concentrations ranged from 2.72 pg/mL to 6.35 pg/mL with a mean of 3.84 ± 0.20 pg/mL in group I and from 0.78 pg/mL to 3.03 pg/mL with a mean of 1.84 ± 0.22 pg/mL in group II. Therefore, plasma endothelin-1 levels of the patients with pulmonary hypertension were significantly greater than those of the patients without pulmonary hypertension ($p < 0.05$) (Table 3). The preoperative plasma endothelin-3 concentrations were 0.64 ± 0.11 pg/mL in group I and 0.71 ± 0.15 pg/mL in group II. The plasma endothelin-1 concentrations of the normal volunteers (ranging from 1.33 to 3.01 pg/mL with a mean of 1.76 ± 0.16 pg/mL) showed a statistically significant difference between the

Table 3. Plasma Endothelin Concentrations

Group	Plasma ET-1 level (pg/mL)			Plasma ET-3 level (pg/mL)		
	Preoperative	Postoperative	Change	Preoperative	Postoperative	Change
With PHT (n = 22)	3.84 ± 0.20 ^a	1.66 ± 0.09 ^b	2.18 ± 0.20	0.64 ± 0.11	0.75 ± 0.06	-0.10 ± 0.12
No PHT (n = 10)	1.34 ± 0.22	1.49 ± 0.12	0.35 ± 0.20	0.71 ± 0.15	0.85 ± 0.17	-0.14 ± 0.26

^a $p < 0.05$ compared with control group. ^b $p < 0.05$ compared with preoperative data.

ET = endothelin; PHT = pulmonary hypertension.

normal volunteers and the patients with pulmonary hypertension ($p < 0.05$), but there was no significant difference between the normal volunteers and the patients without pulmonary hypertension ($p > 0.05$). There was also no significant difference in plasma endothelin-3 levels between group I, group II, and normal volunteers (0.79 ± 0.13 pg/mL).

Cardiac output had a inverse linear correlation with plasma endothelin-1 levels (Fig 1). Pulmonary capillary wedge pressure was positively correlated with plasma endothelin-1 levels (Fig 2), and positive linear correlations also existed between plasma endothelin-1 level and hemodynamic indicators of severity of pulmonary hyperten-

sion such as pulmonary vascular resistance (Fig 3) and mean pulmonary arterial pressure (Fig 4). Similarly, there were significant correlations between plasma endothelin-1 level and the preoperative functional class (Fig 5; Table 4). No significant correlation existed between plasma endothelin-1 levels and systemic arterial pressures, type of valvular lesions, or surgical procedures. Neither could significant correlation be observed between the plasma endothelin-3 levels and such parameters as indicators of severity of pulmonary hypertension, cardiac output, preoperative functional class, systemic arterial pressure, type of valvular lesions, or surgical procedures. Fifteen patients had a xenograft tissue valve failure,

Fig 1. Preoperative cardiac output (CO) had a linear correlation with plasma endothelin-1 (ET1) levels ($p < 0.05$).

Fig 2. Preoperative pulmonary capillary wedge pressure (PCWP) had a linear correlation with plasma endothelin-1 (ET1) levels ($p < 0.05$).

Fig 3. Preoperative pulmonary vascular resistance (PVR) had a linear correlation with plasma endothelin-1 (ET1) levels ($p < 0.05$).

Fig 4. Preoperative mean pulmonary arterial pressure (MPAP) had a linear correlation with plasma endothelin-1 (ET1) levels ($p < 0.05$).

whereas 17 patients had a native valve lesion. No significant difference in plasma endothelin-1 concentrations and plasma endothelin-3 can be demonstrated between the group with xenograft tissue valve failure and the group with native valve lesion (Table 5).

After surgical correction of the valvular lesion, the pulmonary arterial pressure of all patients in group I decreased into the normal range. The plasma endothelin-1 levels ranged from 1.11 pg/mL to 2.60 pg/mL with a mean of 1.66 ± 0.09 pg/mL in group I. Compared with the preoperative value (3.84 ± 0.20 pg/mL), the plasma endothelin-1 level decreased significantly ($p < 0.05$) (Fig 6). There was no statistically significant difference in plasma endothelin-1 and endothelin-3 levels between the normal volunteers and the patients in both group I and group II during the postoperative period (see Table 3). The reduction in pulmonary arterial pressure after surgical correction of the valvular lesion in patients with pulmonary hypertension was always associated with a decrease in plasma endothelin-1 level.

Clinical status of all patients in this study has improved. Thirty patients are in functional class I and 2 in class II. The improvement in functional class was always associated with a decrease in plasma endothelin-1 level in patients with pulmonary hypertension.

Comment

Endothelin is a novel vasoconstrictor peptide composed of three iso peptides (endothelin-1, -2, and -3), each of

which has a unique sequence of amino acids. Endothelin-1 is synthesized by vascular endothelial cells; endothelin-3 is present in a porcine brain homogenate and may be

Fig 5. Plasma endothelin-1 (ET-1) level significantly elevated as the functional class increased ($p < 0.05$).

ET = endothelin.

a neuronal form of endothelin; endothelin-2, however, has not been identified in any tissue. Because endothelin-3 and endothelin-1 can exert potent vasoconstrictive effects on pulmonary arteries [13], they were thought to play a role in pulmonary physiology. Our results clearly demonstrated that the fluctuation of plasma endothelin-1 levels, but not endothelin-3, was concomitant with the severity of pulmonary hypertension. This pointed out the possibility that (1) vascular endothelial cells were the major source of plasma endothelin secreted in patients with pulmonary hypertension and (2) endothelin-3 had little interrelation with the occurrence of pulmonary hypertension.

Our results clearly demonstrated that preoperative plasma endothelin-1 levels were elevated in patients with pulmonary hypertension after valvular heart disease. Steward and associates [14] had a similar result. They pointed out that plasma endothelin-1 levels were elevated not only in patients with primary pulmonary hypertension, but also in patients with secondary pulmonary hypertension associated with hypoxic lung disease, congenital heart disease, collagen vascular disease, pulmonary thromboembolism, and valvular heart disease. The cause resulting in elevation of plasma endothelin-1 level is not yet known. Some authors suggested that the elevation of plasma endothelin-1 level was related to a decrease in its clearance in the lungs. However, as both endothelin-1 and endothelin-3 were cleared mainly through the pulmonary circulation [15], the constant level of endothelin-3 in plasma, as shown in Table 1, indicated that the clearance rate of endothelin in the lung was not impaired in patients with pulmonary hypertension.

There are two possible explanations for the elevated plasma endothelin level in pulmonary hypertension. One possibility is that elevated levels of plasma endothelin might be caused by an increase in metabolic rate of endothelial cells in the pulmonary circulation. The basal

replication rate in the normal vascular endothelial cells is usually 0.15% [16]. Increased endothelial replication has been described in endotoxemia [17] as well as during hypertension [16]. Previous studies have also revealed that plasma endothelin-1 concentrations were elevated both in patients with hypertension [10] and in rats intravenously administered endotoxin [18]. The increased metabolic rate of vascular endothelial cells may facilitate the synthesis of endothelin. Although endothelial cells in pulmonary circulation do not proliferate in pulmonary hypertension, they probably increase their rates of degradation and production. The increase in metabolic rate of endothelial cells in the pulmonary circulation might accelerate the synthesis of messenger RNA of endothelin and its related protein end-product, and thus increase the plasma levels of endothelin-1.

Another explanation for elevated plasma endothelin-1 level is the flow stasis in the pulmonary circulation after pulmonary venous hypertension. Wagner and colleagues [19] observed that plasma endothelin-1 concentrations increased significantly within 10 minutes after venous stasis in the forearm had occurred. The similar result of our study to Wagner's, although the conditions were different, clearly demonstrated that venous hypertension induced through venous obstruction increased the plasma endothelin-1 levels. The increased secretion rate of endothelin might be a result of the interaction between other vasoactive substances and vascular endothelial cells.

Elevated plasma endothelin-1 levels may play an important physiological role in pulmonary hypertension. Unlike the systemic vascular bed, in which both vasodilation and vasoconstriction control blood flow, the pulmonary vascular wall is controlled mainly by vasoconstriction. Under normal conditions, pulmonary vasculature is nearly maximally dilated to permit gas exchange. Prostacyclin may play a role in maintaining this normal level of low pulmonary vascular tone. A previous study [2] has

demonstrated that pulmonary arterial pressure and pulmonary vascular resistance decreased markedly in patients with pulmonary hypertension who received an intravenous infusion of prostacyclin. Recent reports have indicated that endothelin stimulates the release of prostacyclin. Resink and Scott-Burclen [20] revealed that phospholipase A_2 can be activated by endothelin, causing metabolism of arachidonic acid to occur via the lipooxygenase pathway. De Nucci and associates [12] reported that the infusion of endothelin into the perfused lung induced an increase in the level of a stable metabolite of prostacyclin, 6-keto-prostaglandin $F_{1\alpha}$. Furthermore, Fola and associates [21] observed that endothelin had significant dilatory properties that were opposed by its constrictor action at higher doses. They also noted that endothelin-induced dilation in vessels occurred through a cyclooxygenase product-mediated mechanism. In our present experiment, plasma endothelin-1 concentrations were elevated up to 6.35 pg/mL, nearly four times the control levels in patients with pulmonary hypertension; however, the elevated plasma endothelin-1 concentrations were still below the threshold for the induction of vasoconstriction in humans [7]. This peptide, secreted in patients with pulmonary hypertension, may result in prostacyclin secretion, pulmonary vasodilation, and then a decrease in pulmonary vascular resistance.

On the other hand, elevated plasma endothelin-1 levels may be correlated with proliferation of the cells of the vessel wall in pulmonary hypertension. The morphology of the lungs in pulmonary venous hypertension after mitral valve disease is distinctive, and the veins, arteries, and parenchyma are affected. Medial hypertrophy and proliferation of smooth muscle cells are inevitably seen in

veins and arteries in the pulmonary circulation. Komuro and associates [22] reported that endothelin-1 can cause smooth muscle cells to proliferate. The increased secretion of endothelin from endothelial cells may stimulate and further aggravate pathological changes in underlying intima and media of pulmonary vasculature in pulmonary hypertension.

The elevation of pulmonary arterial pressures is observed in many patients with mitral or aortic valve disease. This is a combined result of the back-transmission of elevated left atrial pressures and elevated pulmonary vascular resistance. Our data demonstrated that after surgical correction of the defective valve, severe pulmonary hypertension will regress toward normal, most probably due to the sudden reduction of left atrial pressures and to the reversal of severe spastic pulmonary vasoconstriction that accompanies left atrial hypertension in some patients. Although this initial reduction appears rapidly in most patients, pulmonary vascular resistance sometimes will continue to fall further in the months after operation [23]. Because hemorrhage and surgical procedures resulted in a high level of plasma endothelin [24], the postoperative samples were collected 3 months after operation to avoid interference. Our data showed that plasma endothelin-1 levels and pulmonary arterial pressures synchronously elevated in patients with valvular heart disease according to the severity of pulmonary hypertension, and both of them decreased soon after surgical correction of the diseased valve in the heart. The reversible change in plasma endothelin-1 levels indicated that endothelin-1 was a reactive mediator the release of which was stimulated by the altered resistance of pulmonary venous drainage. Because (1) the maximal plasma endothelin-1 levels in patients with pulmonary hypertension were far below the concentrations required for inducing vasoconstriction; (2) most patients with uremia, diabetes mellitus, and vasculitis had increased plasma endothelin-1 levels [25] without elevated pulmonary arterial pressures; and (3) the elevated plasma endothelin-1 levels in patients with pulmonary hypertension returned to the levels seen in normal control subjects after decrease of pulmonary arterial pressure, we consider endothelin-1 to be a reactive mediator of vasoconstriction in pulmonary hypertension rather than a triggering factor of pulmonary hypertension.

Founded almost two decades ago, Sorin Biomedica S.p.A. has become one of the world's leading manufacturers of innovative cardiovascular technology with a special emphasis on oxygenators, heart valves, pacemakers, vascular grafts, immunodiagnostics and biocompatible materials. The company's entrance into the U.S. market through the acquisition of Shiley, Inc., and the resultant creation of Sorin Biomedical, Inc., in early 1992 gives clinicians across the country access to a much wider array of pioneering new products than ever before.

Introducing The MONOLYTH Uncompromising Design From Top To Bottom.

With most oxygenators, you have to give up something to get something. Compromise is a typical part of the performance equation.

The new Monolyth, however, is not a typical oxygenator. Because its innovative mat fiber design with uniform, equally spaced fibers promotes exceptional gas transfer performance and a remarkably low pressure drop.

The Monolyth also incorporates a unique flow path that runs perpendicular to the bundle, plus a bubble trap for

greater efficiency and safety. Along with an uncompromising heat exchanger. And a compact, low-prime design that helps take performance to an entirely new level.

So what you get is an oxygenator that reflects our constant commitment to technology that is not only state of the art. But technology that takes the art of perfusion to an entirely new state.

For more information, contact your Sorin representative today. And start experiencing the ultimate performance course.

THE CHEVRON-GROOVED, CLOSELY PACKED, PLEATED SHEET OF THE MONOLYTH'S HEAT EXCHANGER ENHANCES BLOOD MIXING WITHOUT HEMOLYTIC TURBULENCE. THIS THIN, STAINLESS STEEL, EPOXY-COATED SHEET TRANSFERS HEAT TO THE THIN BLOOD FILM WITH REMARKABLE EFFICIENCY. AND A UNIQUE FAIL-SAFE DESIGN PREVENTS THE POSSIBILITY OF A SEAL-RELATED WATER LEAK FROM ENTERING THE SYSTEM.

THE MONOLYTH'S EXCEPTIONAL PERFORMANCE IS MATCHED BY ITS EXCEPTIONAL SAFETY. AS BLOOD FLOWS DOWNWARD, NATURAL BUOYANCY HOLDS AIR IN THE BUBBLE TRAP AT THE TOP OF THE UNIT, WHERE IT'S FORCED OUT OF THE UNIQUE MONOLYTH PURGE PORT. THE RESULT? MONOLYTH WAS RATED BEST IN AIR REMOVAL,* FOR AN ADDED LEVEL OF CONFIDENCE IN EVERY PROCEDURE.

THE MONOLYTH ACHIEVES HIGH OXYGENATION PERFORMANCE AND LOW PRIMING VOLUME THROUGH A REVOLUTIONARY MAT FIBER DESIGN WITH UNIFORM, EQUALLY SPACED FIBERS, PLUS A SHORT, NORMAL CROSS PERPENDICULAR FLOW PATH. IN FACT, THE MONOLYTH PROVIDED THE LOWEST PRESSURE DROP OF ANY OXYGENATOR TESTED.*

THE CLEAR HOUSING OF THE MONOLYTH GIVES PERFUSIONISTS EXACTLY WHAT THEY WANT—COMPLETE VISIBILITY AND CONTROL OVER EVERY ASPECT OF EVERY CASE.

A UNIQUE ARTERIAL STOPCOCK FUNCTIONS AS A RECIRCULATION PORT, SHUNTING BLOOD BACK TO THE VENOUS RESERVOIR FOR EASIER PRIMING, AIR REMOVAL, RE-OXYGENATION OR RECIRCULATION. EQUALLY IMPORTANT, IT INCORPORATES A LUER POS-LOK TO FACILITATE BLOOD CARDIOPLEGIA, HEMOCONCENTRATION AND POST-PROCEDURE BLOOD RECOVERY.

With The
MONOLYTH,
Superior
Performance
Is A Matter
Of Course.

Primary Closure for Infected Dehiscence of the Sternum

J. Ernesto Molina, MD, PhD

Department of Surgery, University of Minnesota, Minneapolis, Minnesota

I propose a new irrigation-suction system to achieve primary closure of the sternum in cases of postoperative infected dehiscence. Of 16 cases, I had no treatment failures, no recurring infections, and no patient deaths after 1 to 8 years of follow-up. The new system entails retrosternal and superficial sets of tubes,

both in double-staggered position, with primary closure of the sternum and of the skin. Skin or muscle flaps are avoided, and the stability of the chest cage is maintained. Hospitalization time is 14 to 18 days.

(*Ann Thorac Surg* 1993;55:459-63)

Managing purulent sternal infections with dehiscence and mediastinitis has received frequent attention during the past few years [1-8]. Dehiscence of the sternotomy after cardiac procedures without infection is simply taken care of by rewiring and proper prophylactic antibiotics. However, dehiscence with infection is a more complex problem and has led to a wide variety of treatments.

This condition carries significant mortality even at present [8-10]. Despite successful reports in the literature using primary reclosure, all described techniques have a high failure rate [2, 7, 11-14]. Many cardiac surgeons do not even attempt treatment without consulting plastic surgeons, who usually use muscle, omental, or skin flaps to fill the gap of the dehiscence [1, 2, 5, 12, 15, 16]. This means long hospitalization, complex operation, and chest cage instability until the healing is completed. Any future cardiac reoperation is difficult or impossible.

I contend that all these cumbersome procedures can be totally averted by implementing an aggressive approach as soon as the complication is diagnosed. My approach uses a new irrigation-suction system, combined with an effective rewiring technique described in the next section.

Material and Methods

I treated a total of 16 consecutive patients in whom purulent sternotomy dehiscence developed between 1982 and 1991 at the University of Minnesota with this new approach. During the same period, 6,530 patients underwent open cardiac operations using a midline sternotomy incision (rate of purulent sternotomy dehiscence, 0.24%). Patient age ranged from 17 months to 73 years. Diagnosis of the infection was made from 5 to 46 days after the original operation. I excluded from this study patients who sustained sternotomy dehiscence without infection

and thus were promptly rewired without any complications.

The cardiac procedures the patients underwent are listed in Table 1. Infective organisms were identified as *Staphylococcus aureus* or *Staphylococcus epidermidis*, which comprised 62.5% of the cases (10 patients). The next most frequent organism was *Enterococcus* at 12.5% (2 patients), followed by *Enterobacter* at 12.5% (2 patients), and mixed flora at 12.5% (2 patients). All patients were treated with the same irrigation-suction system, except that smaller tubes were used in children.

Surgical Technique

As soon as the diagnosis was made, the patients underwent operation on an urgent basis. Before the operation, they began receiving intravenous antibiotics. The most common antibiotic used was cefamandole at the dosage of 2 g intravenously every 6 hours for 2 weeks. Other antimicrobial agents were used in the remaining patients according to the organism sensitivity.

Under general anesthesia, the sternotomy was totally reopened. Pressurized water jet irrigation-debridement with antibiotic solution (usually cephalothin at 0.1% concentration) was carried out. I used the Sumpulse lavage system manufactured by the Davol Company (Cranston, RI), with a splash shield 16.5 cm in diameter. The system is connected to a compressed air tank to give the jet of water the proper strength to mobilize the necrotic material. The undersurface of the sternum is surgically mobilized to the lateral border, passing it for about 1.25 cm. If the infection has been present for more than a week, this maneuver is usually very tedious and difficult to do. However, with careful hemostasis using the cautery, it has always been accomplished without complications.

Owing to the absence of tissue planes beyond 2 weeks after operation, no blunt dissection should be attempted. This could tear either the cardiac tissue or other soft structures in the anterior mediastinum; consequent bleeding is difficult to control. Therefore, sharp dissection with cautery is recommended until the entire undersurface of the sternum is completely detached from the mediastinal

tissues and the heart. After both sides are completed in this manner, the anterior surface of the sternum must be laterally exposed using dissection and irrigation. Only the intercostal spaces are needed to allow a reinforcing wire to be placed and laced around each rib, up to the manubrium and back as described by Robicsek and associates [17]. Their technique was originally aimed at preventing sternal dehiscence (Figs 1, 2).

After the mediastinum has been thoroughly irrigated with antibiotic solution and debrided, a deep system of irrigation and suction tubes is implanted. The tubes are staggered to ensure effective irrigation and suction along the entire length of the sternum. Two sets of tubes must be implanted: one deep behind the sternum and one superficially over the sternum between it and the skin.

The irrigation tubes are usually small, 14F or 16F, and the suction tubes are 24F to 28F. To effectively irrigate the upper part of the understernum, an irrigation tube is needed with an accompanying staggered suction tube at that level. Another similar pair is placed to provide irrigation to the lower part of the retrosternum (Fig 3). To avoid confusion for the nursing personnel and house staff, all tubes from the deep system (retrosternal) are always brought out on the right side in the upper part of the abdomen. Tubes are secured to the skin, making sure they are not displaced and remain staggered. Then the sternum is closed. New encircling wires are passed laterally to the longitudinally reinforcing wires in each intercostal space (see Fig 3).

If the patient is large or obese, a double encircling loop of wire could be used at each level so that the sternum is quite stable and firm. The second irrigation-suction system of four tubes is then laid over the sternum and under the skin. The same technique of staggering the chest tubes in the upper and lower half of the sternum is used (Fig 4). All the tubes of the superficial system are brought out through the skin on the left side of the upper abdomen to separate them from the deep system.

Finally, the skin is approximated using monofilament suture in a running or interrupted fashion over the superficial irrigation-suction system. All the irrigation catheters are provided with a three-way stopcock. An antibiotic solution, usually cephalothin at 0.1% concentration, is continuously dripped in each of the irrigation catheters at the rate of 20 mL/h. It is better to have one irrigation bag for each tube, rather than Y-connectors

Fig 1. Lateral reinforcement of the sternum is begun at its distal end, passing the wire around the ribs until the manubrium is reached.

Fig 2. The same wire is brought down, encircling each rib from the opposite side until the distal end is again reached, with the wire twisted and buried.

joining several tubes. This is due to uncertainty over how much of the solution is flowing into each tube.

The suction catheters are connected to a disposable drainage unit, separating the deep system to one unit and the superficial system to a separate unit. The total amount of fluid drained per day is about 1,000 mL per system. Thus, the thoracic drainage (Pleur-evac; Deknatel, Fall River, MA) units are changed every 3 days. If a more economical or convenient suction is preferred, an Emerson large-bottle system (J. H. Emerson, Cambridge, MA) could be used instead.

Length of Treatment

The patient receives intravenous antibiotics every 2 hours during the operation, and then every 6 hours after leaving

Fig 3. The deep system of irrigating tubes is positioned in a staggered manner, behind the sternum and behind the new encircling sternal wires. All tubes of the deep system are brought out on the right side of the upper abdomen.

the operating room. The operation lasts from 1.5 to 2.5 hours. The irrigation-suction system is enforced without changes or interruptions for 7 days. Even if the return fluid looks clear and the patient is afebrile, it takes 7 days for all the spaces in the mediastinum to fill in until only the tube tracts are present. Therefore, this rule is strictly enforced.

At the end of 7 days, the irrigation is stopped. All irrigation catheters (two superficial and two deep) are removed. The suction catheters are left in exactly the same position; no changes are made for 48 hours. The suction catheters are then gradually advanced every 48 hours over 8 days. In this manner, the tubes are totally removed at the end of 8 days. At that point, administration of the intravenous antibiotic is discontinued, and the patient begins receiving oral antibiotics and is discharged, returning to the outpatient clinic 2 weeks later. The monofilament suture holding the skin edges together is left in place for a total of 2 weeks (occasionally 3 weeks).

At the end of that period, administration of all medications is discontinued. The skin sutures are removed and the patient is followed up at monthly intervals.

Results

Regardless of the time or severity of the infection, I have had no treatment failures, no recurring infections, and no patient deaths throughout my observation period of up to 8 years. None of the patients had to be kept on prolonged respiratory support. The sternum was stable from the time of reoperation. Sternal osteomyelitis did not develop in any of the patients. Hospitalization time varied from 14 to 18 days, and no residual problems have been found.

This method is fully effective in healing infected sternotomy dehiscences. It avoids the use of muscle flap and extensive grafting, shortens hospitalization, and maintains the stability of the chest cage. No reoperations have been required.

Comment

When infection of the sternotomy incision develops and signs of mediastinitis with sepsis appear, the heart surgeon usually hesitates to attempt another primary closure, and often refers the patient to a plastic surgeon for debridement and repair. The plastic surgeon, on the other hand, usually assumes that all attempts to put the sternum back together are out of the question, and so plans a reconstructive procedure with soft tissues [1, 2, 12, 18, 19].

I firmly believe this is not necessary in most cases, if the technique I describe is used. The question of sternum viability was raised in only 1 of our patients, whose sternum was under a pool of purulent material. A technetium 99m bone scan showed proper uptake. Therefore, I was able to repair the sternum, and the patient healed without any problems.

The first step toward decreasing the rate of sternotomy dehiscence and infection is prevention. When the original sternotomy is made, it must be done properly, in the center, especially if the patient has a weak or unevenly

Fig 4. The sternum is closed with encircling wires placed lateral to the longitudinal reinforcing wires. The superficial suction-irrigation system is laid over the sternum in a staggered manner. Skin and subcutaneous tissue are closed in one layer with monofilament sutures. Insert: A cross section of the repair showing various planes. (H = heart; L = lungs; Pr = Prolene [Ethicon, Somerville, NJ] suture; R = ribs; W = encircling wire around reinforcing wire parallel to sternum.)

shaped sternum, osteoporosis, or soft bone substance. When there is a question of sternal weakness, I have prophylactically used the Robicsek technique [17] described several years ago. I have not experienced any failures using his technique. This prophylactic closure may also be advisable when both internal thoracic arteries have been taken down and the patient fulfills the criteria described by Kouchoukos and associates [9] of high risk for dehiscence; decreased sternal blood flow has been pointed out by Arnold [20] and Palmer and Taylor [21] as a possible factor leading to dehiscence.

The hospital charge for patients with a dehiscent sternum, infected or not, is about 2.8 times greater than for an uncomplicated case [3, 8]. Furthermore, when a plastic surgeon gets involved in repairing this open wound with muscle or skin flaps, the patient is left with an unstable sternum with soft tissue in front of the heart—even if the repair is successful. Hospitalization is prolonged. Reoperation, if needed later, is very difficult. The mortality rate with an infected sternotomy dehiscence ranges from 15% to 50%, and morbidity is also significant. Therefore, whenever the condition is diagnosed, it should be approached aggressively and promptly with an effective technique.

Loop and colleagues [8] recently described four approaches to treat sternal dehiscence. They reported a 17% failure rate with debridement and primary closure, requiring reexploration for sternal instability or persistent sepsis. Previous reports from other authors showed the same problems with this approach. The reason, I believe, is a defectively designed or suboptimally used irrigation-suction system.

A single chest tube, no matter how large, will not work effectively, particularly if multiple holes are made in the tube from the level of the manubrium to the xiphoid. Most commonly, only the bottom holes will stay open, and the upper areas of the sternum will not be treated at all. I contend that placing a single tube is ineffective.

Engelman and co-workers [11] reported a 33% mortality rate using irrigation-suction techniques. The duration of dehiscence in their patients was the same as in mine, from 8 to 42 days. The mediastinal space was drained and irrigated by using only one tube in the retrosternal position and two tubes in the superior mediastinum used for irrigation. They did not laterally reinforce the already weak sternum, and therefore the dehiscence recurred. In their series, several patients were diagnosed too late. No subcutaneous irrigation system was used in any of their patients.

In the cases reported by Bryant and associates [5], the same deficiencies can be found in the irrigation-suction system design. The method described by Shumaker and Mandelbaum [22] suffered the same shortcoming. Cohen and associates [7] also reported failures using a single-tube system. Culliford and colleagues [23] had similar failure rates.

More recently, Ko and associates [24] achieved preliminary success using debridement with closed irrigation. However, the wound in 3 of 14 patients was converted to an open wound and 1 patient died. The irrigating system used was the same type reported by Culliford and colleagues in 1976.

Wray and co-workers [25] treated dehiscence without irrigation. Most of their patients already had osteomyelitis

of the sternum, which implies a late diagnosis. The use of closed mediastinal irrigation reported by Jurkiewicz and associates [12] also had a high failure rate (in 14 of 25 patients), and muscle flaps were subsequently used.

A similar report was made by Majure and colleagues [6] in treating advanced osteomyelitis of the sternum. Scully and associates [2] compared irrigation and closure by mobilizing pectoral muscle versus leaving the incision open and packed for several days before closure; they used povidone-iodine irrigation, which may explain some of the treatment failure with irrigation and closure.

Povidone-iodine has already been proved highly toxic to serosal surfaces, namely peritoneum, by Ahrenholz and Simmons [26]; it is likely to cause the same degree of damage in the pleura and pericardium. In addition, it is highly toxic to the fibroblasts at the concentrations that have bactericidal effects. Povidone-iodine also impairs the chemotaxis of the neutrophils and kills them at the concentration of 1:10 [27]. In addition to these undesirable local effects, povidone-iodine has been reported to be absorbed, causing iodine intoxication and possibly death [28, 29].

Lineaweaver and associates [27] also found that other types of solutions used frequently in wound care (such as hydrogen peroxide at 3% concentration, sodium hypochlorite at 0.5%, or acetic acid at 0.25%), are highly unsuitable due to their tissue toxicity and their ineffectiveness in topically controlled infections. Yet, antibiotic solutions at various concentrations were never found to damage human fibroblasts or neutrophils.

Based on my experience as well as the literature, I agree with Ochsner and associates [14] that muscle flaps and soft tissue should have very limited application in sternotomy dehiscence. After a prompt diagnosis, an aggressive and effective technique must be implemented to simultaneously treat the infection and the dehiscence. The irrigation-suction system I describe, even when applied late, is a very effective first-line approach to combat this complication.

Effect of Methylprednisolone and Prostacyclin on Bronchial Perfusion in Lung Transplantation

Kenji Inui, MD, Hans-Joachim Schäfers, MD, Minoru Aoki, MD, Hiromi Wada, MD, Vera Becker, Birte Ongsieck, and Axel Haverich, MD

Division of Thoracic and Cardiovascular Surgery, Surgical Center, Hannover Medical School, Hannover, Germany, and Kyoto Chest Disease Research Institute, Kyoto University, Kyoto, Japan

In an experimental investigation using modified unilateral lung transplantation in pigs, the effects of systemic administration of methylprednisolone and prostacyclin on bronchial mucosal blood flow were assessed. Laser Doppler velocimetry (LDV) and radioisotope studies using radiolabeled erythrocytes (RI) were employed to measure blood flow at the donor main carina and upper lobe carina after 3 hours of reperfusion. The recipient carina was used as a reference point. Five groups of 6 animals each were studied. Group I served as control. In group II, methylprednisolone (20 mg/kg) was administered to the recipient. In group III, prostacyclin ($4 \text{ ng} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) was given to the recipient, and in group IV, prostacyclin (100 μg intravenously) was administered to the donor. In group V, prostacyclin was

given to the recipient and the donor animals as in groups III and IV, respectively. In group I, bronchial blood flow at the donor main carina was $37.6\% \pm 2.2\%$ (LDV) and $44.1\% \pm 14.8\%$ (RI) of reference blood flow. No significant differences were found between the controls and groups II, III, and IV. In group V, bronchial blood flow was markedly increased both at the donor main carina (LDV, $39.8\% \pm 6.2\%$, $p = 0.12$; RI, $55.7\% \pm 11.4\%$, $p < 0.2$) and the donor upper lobe carina (LDV, $65.8\% \pm 5.4\%$, $p < 0.05$; RI, $76.8\% \pm 21.3\%$, $p < 0.2$). We conclude that systemic administration of prostacyclin to the donor and recipient results in marked improvement of bronchial blood flow and may reduce the incidence of bronchial complications after lung transplantation.

(*Ann Thorac Surg* 1993;55:464-9)

Unilateral and bilateral pulmonary transplantation have become a realistic option for many patients with terminal pulmonary disease and preserved cardiac function [1-4]. Airway complications, however, are still important sequelae of lung transplantation, occurring in 10% to 20% of patients after unilateral and bilateral lung transplantation.

A number of experimental investigations have identified ischemia of the donor bronchus as the most important factor for the occurrence of bronchial complications [5-7]. Deprived of its physiologic blood supply the transplanted airway depends on retrograde perfusion from bronchopulmonary collaterals before bronchial vessels bridge the anastomosis [8, 9]. An omental wrap around the bronchial connection has not been able to uniformly prevent ischemia of the transplanted airways [10]. Direct revascularization of a bronchial artery has been proposed [6, 7, 11, 12]; however, it is technically difficult, it may not be possible in all patients due to variable anatomy of the bronchial vessels [13], and its long-term patency may be questioned [14]. Furthermore, we have previously shown that despite adequate revascularization of a bronchial artery, blood flow may still be subnormal, suggesting a defect in the microcirculation of the transplanted bronchus [15].

We have previously shown in a model of modified unilateral lung transplantation that blood flow at the donor main carina ranges around 35% to 40% of normal airway perfusion [15]. The objective of the present investigation was to verify whether bronchial blood flow can be increased by means of systemic administration of drugs that can be expected to improve the graft microcirculation. Methylprednisolone was chosen for its beneficial effects on leukocyte aggregation and complement activation, possibly limiting reperfusion injury [16]. Prostacyclin has been shown to result in superior postoperative graft function when given to the donor before flushing of the lungs [16]. In addition, prostaglandins appear to play an important role in the regulation of bronchopulmonary collateral blood flow [17, 18]. In this study, the potential effects of these agents were assessed in modified unilateral lung transplantation. Bronchial blood flow was measured using laser Doppler velocimetry (LDV) and radioisotope (RI) studies with radiolabeled erythrocytes.

Material and Methods

Model

The technique of unilateral lung transplantation was modified, leaving the entire left main bronchus, the main carina including the origin of the right main bronchus, and the distal trachea in continuity [1]. The airway anastomosis was performed between the left main bronchus of the recipient and the donor trachea. Left upper lobe carina and main carina of the graft were used to measure

bronchial blood flow. The recipient carina was chosen as a reference point.

Animals and Anesthesia

Male pigs with a body weight of 20 to 26 kg were used as donor and recipient animals. All animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-32, revised 1985). The animals were premedicated with azaperone (10 mg/kg intramuscularly), atropine sulfate (0.5 mg intramuscularly), and metomidate hydrochloride (10 mg/kg intravenously) before endotracheal intubation. They were then placed on a respirator (Bennet Respiration Unit MA-1B) with a total volume of 20 mL/kg, a respiratory rate of 15/min, and a positive end-expiratory pressure of 3 cm H₂O. Anesthesia was maintained with 50% oxygen, 50% N₂O, and intravenous injections of fentanyl (0.2 mg), metomidate hydrochloride (200 mg), and pancuronium (4 mg). The respiratory rate was adjusted to achieve an arterial carbon dioxide tension of 35 to 40 mm Hg.

Operative Technique

The operative technique was identical to that published previously [15]. The chest of the donor animal was opened by median sternotomy, and the heart-lung block was prepared for explantation. Heparin (300 U/kg) was given intravenously, and a perfusion catheter was placed in the pulmonary trunk. After inflow occlusion and cross-clamping of the ascending aorta, the tip of the left atrial appendage was amputated and the pulmonary arterial bed perfused with modified Euro-Collins solution, maintaining a pulmonary arterial pressure of 10 to 15 mm Hg [19]. The heart-lung block was then excised. *Ex situ*, the heart and the right lung were removed, and the stump of the right main bronchus was closed with a running suture. Left pulmonary artery and a cuff of left atrial wall surrounding the left pulmonary veins were prepared for implantation. The graft was then placed in cold (4°C) Euro-Collins solution until implantation.

In the recipient animal, a left thoracotomy was performed through the bed of the resected fifth rib. The lung was mobilized, the hemiazygos vein was ligated and divided adjacent to the pulmonary artery, and the pericardium was incised anterior to the pulmonary veins. The left pulmonary artery was occluded at its origin and divided proximal to the first upper lobe branch. The left main bronchus was clamped and divided central to the upper lobe bronchus. Finally, the left atrium adjacent to the pulmonary veins was excluded with a side-biting clamp. The veins were divided and their orifices connected by an incision, creating a common left atrial orifice.

Implantation was begun with an end-to-end anastomosis of donor and recipient left atrium using a continuous everting mattress suture (5-0 Prolene; Ethicon, Somerville, NJ). An end-to-end anastomosis was created between donor and recipient pulmonary artery (5-0 Prolene). The donor trachea was shortened to three rings superior to the main carina, and an end-to-end anastomosis was created between recipient left main bronchus and

Fig 1. Experimental model: the entire left main bronchus, the main carina including the origin of the right main bronchus, and the distal trachea of the graft (shaded) are left in continuity. The airway anastomosis is performed between the left main bronchus of the recipient and the donor trachea. Bronchial blood flow is assessed at the upper lobe carina and the main carina of the graft (circles); the recipient main carina (circle) is used as reference point.

graft trachea using a running suture (3-0 Prolene). Ventilation was resumed, the pulmonary vascular bed deaired, and the clamps removed.

Measurement of Bronchial Blood Flow

Three hours after reperfusion bronchial mucosal blood flow was measured using LDV (Periflux PF2; Perimed, Stockholm, Sweden). The fiber probe (PF 109 D, Perimed) was introduced through a fiberoptic bronchoscope and guided to the respective measuring points. Under bronchoscopic vision, the laser fiber was placed on the bronchial mucosa, care being taken to obtain a stable signal for at least 10 seconds. This was repeated five times; a mean of these five measurements was calculated and considered as the representative value. Measuring points for each animal were donor main carina and donor upper lobe carina; the recipient main carina was chosen as a reference point (Fig 1). Blood flow was expressed as flow relative to the reference point (donor main carina/recipient main carina, donor upper lobe carina/recipient main carina).

Immediately after completion of the LDV measurements the erythrocytes were labeled *in vivo* using 370 MBq technetium 99m (activation with Technescan PYP; Malinckrodt, Patten, Holland). Fifteen minutes after the injection of technetium 99m, the animal was sacrificed by intravenous injection of T-61 (Hoechst Veterinär, Unterschleissheim, Germany). The central airways of donor and recipient were excised and segments of recipient carina, donor carina, and donor upper lobe carina were removed corresponding to the measuring points of LDV (Fig 2). Radioactivity of the tissue samples was determined in a scintillation chamber and expressed as counts per minute corrected for tissue weight. Relative values were calculated for donor carina and donor upper lobe carina, using the recipient carina as reference.

Experimental Groups

The animals were divided into five groups. Group I ($n = 6$) served as a control group. In group II ($n = 6$) methyl-

Fig 2. Experimental model: after activation of erythrocytes with technetium 99m, segments of donor and recipient airway (dark areas) are excised for determination of radioactivity.

prednisolone was administered intravenously to the recipient animal 10 minutes before reperfusion (500 mg). In group III ($n = 6$) prostacyclin was given as a continuous intravenous infusion ($4 \text{ ng} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), beginning 10 minutes before reperfusion and continuing throughout the observation period. In group IV ($n = 6$) prostacyclin ($100 \mu\text{g}$) was given intravenously to the donor animal before the Euro-Collins flush. In group V ($n = 6$) prostacyclin ($100 \mu\text{g}$ intravenously) was administered to the donor animal and given as a constant infusion ($4 \text{ ng} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) to the recipient animal.

Statistical Methods

Mean values $\pm$ standard deviations were calculated. Statistical comparison between the groups was performed using analysis of variance. A p value of less than 0.05 was considered significant.

Results

Body weight of the experimental animals and hemodynamic data obtained after 3 hours of reperfusion are depicted in Table 1. There was no significant difference between the groups with respect to body weight; therefore, cardiac output measurements were not indexed by the animals' weight. Mean arterial pressure was significantly lower in group III compared with groups I, IV, and V ($p < 0.05$). Concurrently, pulmonary artery pressures were lower in group III than in groups IV and V ($p <$

Fig 3. Bronchial blood flow (Q_{BR}) at donor main carina. Both by laser Doppler (LDV) and radioisotope (RI) studies, an increase in bronchial blood flow is observed only in group V (prostacyclin to donor and recipient). Due to group variability, the differences are not statistically significant [$(*) = p < 0.2$]. (RC = recipient main carina.)

0.05). In group IV, cardiac output was significantly higher than in groups II and III. No significant differences existed between groups I and V with respect to any of the parameters measured.

Three hours postoperatively bronchial blood flow at the donor main carina was markedly decreased in group I (LDV, $37.6\% \pm 2.2\%$; RI, $44.1\% \pm 14.8\%$). In groups II (LDV, $29.2\% \pm 13.5\%$; RI, $35.4\% \pm 7.0\%$), III (LDV, $27.8\% \pm 12.4\%$; RI, $30.8\% \pm 16.2\%$), and IV (LDV, $34.3\% \pm 5.1\%$; RI, $33.1\% \pm 12.3\%$) blood flow at the donor carina was unchanged compared with group I (Fig 3). In group V an increase in bronchial blood flow was observed (LDV, $39.8\% \pm 2.4\%$, $p = 0.12$; RI, $57.1\% \pm 12.3\%$, $p = 0.14$). The increase was not statistically significant due to interindividual variability.

At the donor upper lobe carina, subnormal blood flow also was found in the control group (LDV, $54.9\% \pm 7.7\%$; RI, $61.6\% \pm 25.7\%$). Flow at the upper lobe carina did not show a significant difference between the control group and groups II (LDV, $62.0\% \pm 5.9\%$; RI, $44.0\% \pm 8.1\%$), III (LDV, $58.1\% \pm 3.7\%$; RI, $59.2\% \pm 19.8\%$), and IV (LDV, $57.6\% \pm 5.9\%$; RI, $64.3\% \pm 18.1\%$) (Fig 4). In group V, blood flow was significantly improved compared with the control group (LDV, $66.1\% \pm 5.9\%$; RI, $80.3\% \pm 21.8\%$, $p < 0.05$).

Comment

Airway complications were one of the main causes of death in the early experience with lung transplantation [6, 20]. A number of experimental and clinical observations have indicated that bronchial ischemia is the most important factor responsible for the occurrence of these sequelae of lung transplantation [6, 7, 15]. After transplantation, the grafted bronchus is deprived of its physiologic arterial blood supply and for a period of 3 to 4 weeks depends on retrograde blood flow from bronchopulmonary collaterals [8, 9].

A number of experimental approaches have been suggested to avoid bronchial ischemia. Minimizing dissection

Table 1. Variables Measured in the Five Experimental Groups After Three Hours of Reperfusion

Group	BW (kg)	MAP (mm Hg)	PAP (mm Hg)	CO (L/min)
I	24.5 $\pm$ 1.9	60.8 $\pm$ 9.2	22.7 $\pm$ 11.0	2.6 $\pm$ 0.6
II	23.3 $\pm$ 2.6	56.7 $\pm$ 8.0	19.8 $\pm$ 7.3	2.0 $\pm$ 0.5
III	22.5 $\pm$ 1.7	52.3 $\pm$ 7.3	13.0 $\pm$ 2.9	1.7 $\pm$ 0.6
IV	24.1 $\pm$ 1.9	62.4 $\pm$ 10.2	19.1 $\pm$ 2.5	2.8 $\pm$ 0.8
V	22.2 $\pm$ 2.8	61.8 $\pm$ 9.6	17.5 $\pm$ 4.7	2.5 $\pm$ 0.7

BW = body weight; CO = cardiac output; MAP = mean arterial pressure; PAP = pulmonary artery pressure.

Fig 4. Bronchial blood flow (Q_{BR}) at the graft upper lobe carina. Both laser Doppler (LDV) and radioisotope (RI) studies demonstrate a marked increase in blood flow only in group V (prostacyclin to donor and recipient). As measured by LDV, the difference is significant (* $p < 0.05$); due to group variability, RI did not show a significant increase [(*) = $p < 0.2$]. (RC = recipient main carina.)

around the donor airway [5], choosing an anastomotic site as peripheral as possible on the graft airway [21, 22], using an omental wrap [23], and revascularization of a bronchial artery [6, 7] have been found to reduce the prevalence and severity of bronchial complications in experimental lung transplantation.

The concept of using bronchial omentopexy was introduced into clinical lung transplantation [4, 14]. It was thought that the success of unilateral as well as bilateral lung transplantation could be attributed to the use of the omentum [4]. With increasing experience, however, it became apparent that airway complications still occurred in more than 10% of the patients [10]. Clinical observations indicated that bronchial stenoses were preceded by bronchoscopic evidence of ischemia in the graft airway. These ischemic changes are commonly apparent within the first postoperative week, indicating either inadequate ingrowth of collateral vessels from the omentum or inadequate collateral blood supply.

Direct revascularization of a bronchial artery has been performed experimentally and clinically [6, 11, 12, 14, 22] and results in significant improvement in bronchial mucosal blood flow [15]. Normalization of bronchial blood flow, however, could not be achieved, indicating a possible defect in the microcirculation of the graft [15]. In addition, revascularization of a bronchial artery may be technically difficult and may not always be feasible due to the variable anatomy of the bronchial vessels [13]. Up to now, few investigations have focused on preservation of bronchial or pulmonary microcirculation or improvement of bronchopulmonary collateral flow as an alternative source of bronchial blood supply after transplantation.

The present model was chosen to imitate the clinical situation, in which the graft undergoes the surgical trauma of transplantation and the pulmonary vascular bed is perfused by pulsatile blood flow. The length of the transplanted airway was extended intentionally to provide information on blood flow in the left main bronchus; because in clinical transplantation the airway anastomosis

is performed at this level, information on perfusion of the airway central to the upper lobe bronchus was considered to be of clinical relevance. In addition, investigations on blood flow at the level of the upper lobe carina have demonstrated little difference between normal levels and those achieved after transplantation [24]. Measurement of blood flow using LDV requires placement of the endoscopic probe orthogonal to the surface of the bronchus, making main carina and lobe carinas the only practical measuring points. For this reason, blood flow cannot be measured along the left main bronchus in a position where an anastomosis is placed under normal clinical conditions. Blood flow along the left main bronchus can, however, be extrapolated from proximal and distal measuring points.

Laser Doppler velocimetry was employed as one method for measuring bronchial mucosal blood flow; its value in assessment of blood flow of bronchial mucosa has been documented [5, 25]. A drawback of the system is its inability to measure absolute blood flow. In addition, changes in the pressure with which the endoscopic fiber is held onto the surface may alter the results. Attempts were made to minimize these drawbacks. The use of a reference point (recipient main carina) allowed for determination of relative values without the need for correcting factors between individual experiments. To minimize the effect of airway movements on the results, a stable signal was obtained for at least 10 seconds. The measurements were repeated five times, and the mean value was accepted for analysis. The small interindividual variability within each experimental group indicates that the technique of LDV was used correctly.

The use of radioactive microspheres is an accepted method in assessing relative bronchial blood flow [18, 26]. In this investigation, however, the blood flow to be measured was to pass the pulmonary vascular bed and bronchopulmonary collaterals before entering the bronchial vascular bed. Therefore, it was uncertain whether microspheres at defined diameters would be able to pass the collateral vessels rather than embolizing in the pulmonary capillaries. Thus, labeled erythrocytes were chosen as "microspheres," assuming that they would represent the most reliable indicator of true bronchopulmonary collateral flow to the transplanted airway in the present model. The good correlation between values obtained by LDV and RI indicates that—despite the modification in radioisotope tracers—acceptable data were obtained by RI.

Prostacyclin is a natural prostaglandin with strong vasodilating action on the pulmonary as well as the peripheral arterial bed [27, 28]. Its effect with regard to inhibition of platelet aggregation has been used to decrease platelet consumption during cardiopulmonary bypass and hemodialysis [29]. In experimental pulmonary transplantation, prostacyclin has been found to improve preservation when given to the organ donor before Euro-Collins flush [30]. Corticosteroids can be expected to exhibit a positive effect on graft microcirculation by limiting vascular injury via inhibition of proteolytic enzyme release from polymorphonuclear leukocytes, decreased

platelet and leukocyte aggregation, and increased membrane stability [31].

The results obtained in the control group confirmed that after transplantation perfusion of the transplanted bronchus is subnormal. Compared with the physiologic situation, the central airway receives approximately 35% of its normal blood supply. In addition, the blood derived from bronchopulmonary collaterals is of limited oxygenation, possibly resulting in decreased tissue oxygen tension below critical levels required for survival of tissue and adequate healing. No improved bronchial blood flow was observed after administration of methylprednisolone. This may be due to the fact that the dose employed (20 mg/kg) was relatively small compared with the dose employed in shock (40 mg/kg) [31]. On the other hand, it may also indicate that despite its positive actions on the mechanisms involved in reperfusion injury, the duration of postoperative follow-up or the timing of administration were inadequate to demonstrate a positive effect [31]. Finally, a type 2 error may have prevented detection of differences between groups I and II.

After administration of prostacyclin either to the donor or the recipient animal, no improvement in bronchial blood flow was observed. With combined administration of prostacyclin both to donor and recipient, however, a marked improvement in bronchial blood flow was observed. The level of blood flow was similar to that obtained by direct revascularization of a bronchial artery in a previous investigation [15]. Because no significant difference in the hemodynamic variables measured in groups I and V were observed, this increase in blood flow is unlikely due to general hemodynamic effects of prostacyclin. Rather, an intrapulmonary mode of action, such as increased bronchopulmonary collateral flow, must be assumed. The decrease in blood flow in group III in conjunction with lower pulmonary artery pressures and cardiac output, however, indicate that hemodynamic variables may exert an influence on bronchial blood flow. Relative hypovolemia, which can be assumed according to the hemodynamic data, may result in inadequate bronchial perfusion. Conclusions drawn from this investigation have to be limited due to the low number of experimental investigations in each group. Since completion of the experiments, we have modified our clinical regimen, including combined administration of prostacyclin to donor and recipient. Concurrent with the change in the therapeutic regimen, a decrease in the incidence of bronchial complications has been observed [32].

The results obtained previously [15] indicate that the occurrence of bronchial ischemia may in part be caused by a defect in the graft microcirculation. Little is known about the mechanisms of this defect, because research in pulmonary preservation has mainly focused on graft function with respect to gas exchange. Little information is available on the effects of ischemia and the current preservation methods on the pulmonary vascular compartment. Experimental observations and the experience from renal and hepatic transplantation indicate that the high potassium concentration of Euro-Collins solution may lead to significant vasospasm of the perfused vascular bed.

The improvement in pulmonary graft function after administration of prostacyclin before the Euro-Collins flush may in part be mediated by inhibition of vasospasm and consequent avoidance of inhomogeneous perfusion. Experimental observations also suggest that the endothelial cells may show signs of temporary damage after Euro-Collins flush perfusion and extraction (unpublished data). Inadequate perfusion of the bronchial vascular bed during pulmonary artery flush has been suggested as a possible mechanism of inadequate pulmonary preservation [33]. Using the identical model, we added flush perfusion of the descending thoracic aorta to the pulmonary artery flush and obtained results identical to the control group (unpublished data). Thus, inadequate perfusion and preservation of the bronchial arteries does not appear to be a probable mechanism responsible for the defect in microcirculation. Improved pulmonary preservation may further control the problem of bronchial ischemia after pulmonary transplantation.

Pressure–Volume Relationship of the Fetal Lamb Heart

Sharon R. Weil, MD, Pierantonio A. Russo, MD, James L. Heckman, PhD, Rohinton K. Balsara, MD, Valarie Pasielki, BS, and Jeffrey M. Dunn, MD

Pediatric Heart Institute, Departments of Surgery, Physiology, and Pediatrics, Temple University School of Medicine and St Christopher's Hospital for Children, Philadelphia, Pennsylvania

In contrast to the adult heart, the fetal heart reportedly has little functional reserve. With increased clinical emphasis on fetal cardiac diagnosis, neonatal surgery, and the potential for future fetal cardiac intervention, it is essential that we better understand fetal cardiac function. Therefore, to demonstrate the extent of fetal cardiac preload reserve, we studied 10 fetal lambs using an isolated, isovolumic, blood-perfused heart preparation. We maintained constant afterload, inotropic state, coronary blood flow, heart rate, and perfusate blood gas values. As left ventricular (LV) volume (preload) was incrementally increased, LV end-diastolic pressure and

LV peak systolic pressure were recorded. Linear regression analysis demonstrated that increases in LV developed pressures were predicted by the LV volume, demonstrating the presence of the Frank-Starling mechanism in each case. The plateau of the Starling pressure–volume curve occurred at an LV end-diastolic pressure of 12.5 ± 4.79 mm Hg (95% confidence interval, 9.07 to 15.9 mm Hg), lower than the plateau expected in the adult heart. This implies that, in the management of fetal and immature neonatal hearts, preload reserve plays an important but limited role in cardiac reserve.

(*Ann Thorac Surg* 1993;55:470–5)

Increasing attention is being paid to the clinical aspects of fetal cardiac development, congenital defects, and fetal cardiac function [1, 2]. Recent advances in noncardiac fetal surgery [3–6] have suggested the feasibility and possible advantages of fetal surgical intervention for certain lesions. It is likely that selective fetal intervention for congenital heart lesions will also be beneficial. If we are to properly interpret prenatal cardiac diagnosis and consider managing the fetus surgically, it will be essential to understand fetal cardiac mechanics and the mechanisms we can recruit to optimize fetal cardiac function. In addition, the understanding of fetal cardiac mechanics will help us in the care of neonates in whom cardiac mechanics is in transition between the immature and mature states.

Cardiac preload reserve defines the role of the active length–tension mechanism, or Frank-Starling pressure–volume curve, of the heart. It represents the capacity to increase cardiac output from baseline by increasing preload or cardiac end-diastolic volume. Although many studies have demonstrated little or no preload reserve in fetal myocardium, especially when compared with mature myocardium [7–13], others have demonstrated significant preload reserve in the fetal heart [14–16]. The discrepancy of these results may be secondary to the difficulty in studying the fetal heart. Exteriorized fetal preparations are intrinsically unstable [17]. Although more stable, chronic in utero preparations are difficult to

study because of the investigators' inability to isolate and independently control the major variable determinants of cardiac function: preload, afterload, inotropic state, coronary blood flow, and heart rate.

This study was designed to evaluate the extent of cardiac preload reserve in the fetus using a modified isolated, isovolumic fetal lamb heart preparation. The model developed is stable and allowed us to independently control variables of cardiac function including preload, afterload, heart rate, and coronary perfusion pressure. In addition, this preparation removes inotropic state and hormonal and neural influences on cardiac mechanics.

Material and Methods

Fetal cardiac mechanics were studied in 10 fetal lambs of 129 to 135 days gestational age (term gestation = 145 to 155 days) to determine the fetal capacity for cardiac preload reserve and to establish the stability of our model.

Animal Preparation

This study was performed using protocols approved by the Institutional Animal Use and Care Protocol Committee of Temple University Medical School. By using a ewe carrying a twin gestation, it was possible to have an ideal donor for blood and two experimental animals. Each pregnant ewe was sedated with ketamine (10 mg/kg intravenously), intubated, maintained on a volume ventilator, and anesthetized with a gas mixture of 30% oxygen and 70% nitrous oxide augmented with continuous intravenous infusion of fentanyl. This anesthetized the fetuses as well as the ewe and avoided the reduction

in inotropic state caused by anesthetics such as halothane or pentobarbital. The ewe was anticoagulated with $3 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ heparin intravenously. The fetal lamb was delivered through a right-sided laparotomy and small hysterotomy, taking care to avoid umbilical cord compression. A fetal median sternotomy was performed, the pericardium opened, the heart exposed, and the fetal innominate artery cannulated with an 8F perfusion cannula. Simultaneously, the ewe's right carotid artery was cannulated to drain 500 mL of maternal blood to prime the isolated perfusion system described below. The fetal inferior and superior venae cavae were divided. When the fetal aortic pressure dropped to 10 to 20 mm Hg, the aortic arch distal to the innominate artery was ligated and the isolated perfusion system instituted, perfusing the fetal aortic root and coronary arteries.

Isolated Heart Preparation

The perfusion system was a closed-loop system consisting of a venous reservoir, heat exchanger, membrane oxygenator (Scimed Life Systems Inc), and a roller pump (Masterflex, N-07520-35) designed to perfuse the fetal heart at 50 mm Hg (Fig 1). The perfusion pump was servo-computer controlled to maintain the chosen constant coronary perfusion pressure of 50 mm Hg, mimicking the in utero systolic pressure, by using the digitized aortic root pressure to continually adjust the Masterflex pump output. In three experiments, constant coronary perfusion pressure was maintained using an elevated arterial line overflow reservoir. Coronary venous and thebesian blood was drained by gravity to the venous reservoir.

After excision of the fetal heart, the fetal blood was collected in a second blood reservoir. When the isolated preparation was stable, the fetal blood was substituted in the circuit for the maternal blood to avoid any effects of adult hemoglobin with its oxygen dissociation curve shifted to the right compared with fetal blood.

Side ports on the perfusion circuit provided for measurement and recording of fetal coronary artery pressure and temperature, and periodic sampling of oxygen tension, carbon dioxide tension, and pH.

A latex elliptical balloon mounted on a 5F single-lumen Millar catheter was inserted into the cavity of the left ventricle through a left atriotomy. It was positioned by a plastic ring on the balloon catheter secured to a mitral annulus pursestring suture. The balloon had an unstressed volume of 6 to 8 mL, much larger than the largest left ventricular (LV) volume. At the completion of each experiment, the left ventricle was dissected with the balloon in place, confirming that the balloon "fit" the ventricle well. The LV apex was vented to drain thebesian flow and decompress the left ventricle of blood. Two epicardial pacing wires were placed on the right ventricular free wall, and the heart was paced at a fixed rate of 180 beats/min.

Determination of Left Ventricular Systolic and Diastolic Pressure-Volume Relationships

Preload was varied in a controlled manner by gradually increasing the LV balloon volume. This was accomplished by increasing the balloon volume by increments of 0.1 or 0.2 mL from V_0 (defined as the volume at which LV end-diastolic pressure [LVEDP] was 0) until no further increment in developed pressure occurred. At balloon volumes near V_0 , small increments in balloon volume changed the LVEDP; thus V_0 was easy to define. At each balloon volume the heart was allowed to stabilize for at least 3 minutes and the LVEDP, LV peak systolic pressure (LVSP), LV developed pressure (LVDP), coronary blood flow, and coronary perfusion pressure were recorded. Increases in LVEDP and LVSP were measured by continuous recording from the Millar catheter in the balloon. Left ventricular developed pressure was calculated at each balloon volume using the equation: $\text{LVDP} = \text{LVSP} - \text{LVEDP}$.

Pressure-volume curves were generated for each fetal heart by plotting balloon volume (corrected for the deflated balloon volume) against LVEDP, LVSP, and LVDP. Dependence of LVDP on LV volume was analyzed by performing linear regression analysis of the LV volume (independent variable) and LVDP (dependent variable) throughout the range of LV volumes from an LVEDP of 0 to the LV volume at which the LVDP reached its plateau.

Results

The long-term stability of this preparation was confirmed in two preparations in which the LV balloon volume, heart rate, and coronary perfusion pressure were held constant for 1 hour. Serial measurements of LVEDP,

Fig 2. Serial left ventricular pressure recording from an isolated fetal heart at a constant ventricular balloon volume recorded at 15-minute intervals over 1 hour. Minimal variation in left ventricular end-diastolic pressure and left ventricular developed pressure demonstrates stability of the preparation.

LVDP, LVSP, and coronary blood flow demonstrated minimal variation (Fig 2).

After each increment in corrected end-diastolic volume, LVSP stabilized within 10 beats. Consistent pressure-volume function relations (Starling curves) were obtained from each fetal heart preparation (Table 1, Fig 3). As LV end-diastolic volume and, therefore, preload, was increased, there was a clear increase in developed pressure until an LVDP plateau was reached, demonstrating the presence of the Starling mechanism, or preload reserve. For each pair of data, linear regression analysis of corrected LV volume (independent variable) and LVDP (dependent variable) consistently demonstrated a statistically significant positive relationship (Table 2). In each case, the linear regression curve defined a line with a positive slope ($176 \pm 75.54 \text{ mm Hg} \cdot \text{mL}^{-1} \cdot \text{g LV weight}^{-1}$). This was highly significant as demonstrated by r^2 and F values (see Table 2) in each case. Linear regression defined a better fit to the data than second- and third-degree curves in each animal.

The plateau of the Starling curve occurred at an LVEDP mean of $12.5 \pm 4.79 \text{ mm Hg}$, with a range from 7 to 22 mm Hg (see Table 1). The 95% confidence limit of LVEDP at the Starling curve plateau was 9.07 to 15.9 mm Hg.

Comment

As we increasingly incorporate fetal diagnosis of cardiac defects into our clinical armamentarium, an understanding of fetal cardiac mechanics will become essential. Basic to our understanding of adult cardiac function is the role of preload reserve, the active length-tension relationship described by Frank and Starling. Preload reserve is of comparable importance for the fetus as it responds to altered cardiac demand associated with stresses such as growth, hypoxia, infections, the birth process, and congenital cardiac lesions. With increasing use of fetal therapy and manipulation, the clinician will have to be able to recruit this reserve when augmentation of fetal cardiac output is indicated. In addition, neonatal cardiac mechanics, especially in the premature neonate, represents a transitional state between fetal and mature cardiac mechanics.

The structural and biochemical characteristics of the

EDP = end-diastolic pressure; DEV PR = developed pressure (PK PR - EDP); NORM VOL = left ventricular (LV) volume normalized for LV weight = LVB balloon volume/LV weight (where LV weight = weight of LV free wall + 1/2 septum); PK PR = peak systolic pressure.

fetal heart change throughout gestation. As normal development progresses in the embryo and fetus, many changes occur in structure and biochemical properties, including increases in the numbers and cross-sectional area of cardiac myocytes, increases in myofibrillar density, development of transverse tubules, development of sarcoplasmic reticulum, growth of the coronary arteries, an increase in myosin adenosine triphosphate activity, a change in myofilament sensitivity to calcium, and a decrease in glycogen level [18-20]. Although these changes in structural and biochemical properties strongly suggest that there are major alterations in mechanical function associated with normal development, we know of no studies that have correlated these structural changes with preload, afterload, and functional mechanics in the fetal heart.

In contrast to the adult heart, the fetal heart has been reported to have little functional reserve. Rudolph and others have suggested that increases in preload produce little or no increase in cardiac output [7-13]. Others, however, have demonstrated the length-tension response both in isolated muscle strip preparations and in the intact fetus [14-16, 21]. In our experiment, the Starling curve peaked at an LVEDP of 7 to 22 mm Hg (95% confidence interval, 9.07 to 15.9 mm Hg), which correlates well with the data of Kirkpatrick and associates [14], who found that the developed pressure peaked at an LVEDP of about 10 mm Hg. The lack of preload reserve found by some investigators may be explained by the fact that the resting LVEDP of the fetal heart is close to the LVEDP that produces peak LVDP. Thus, although the fetal heart exhibits a clear Starling mechanism, it may be unable to recruit reserve function because it functions near the peak of the curve at rest.

Fig 3. (A) Representative pressure-volume curve from fetal heart 3. (B) Starling curves from each of the 10 isolated fetal hearts. (Closed circles = left ventricular peak pressure; open circles = left ventricular end-diastolic pressure; open triangles = left ventricular developed pressure.)

It is not surprising that the fetal heart works at rest near peak function because the cardiac demands are ever-increasing in the rapidly growing fetus. Indeed, it may be

^a The pressure-volume data are fitted to the "best-fit" linear equation. The equation is in the form: DP = a + b × Vol, where DP = left ventricular developed pressure, Vol = normalized left ventricular volume (mL/g of left ventricular weight), a = Y intercept constant, and b = slope. ^b Hypothesis is tested at 95% confidence limit (Yes = significant).

that the wall stress associated with working at the peak of the Starling curve may be a primary stimulus of fetal cardiac growth in response to body growth. We have no explanation for the low LVEDP for peak LV function in the fetal heart compared with the mature heart. It cannot be explained by compliance, because the fetal heart is less compliant than the mature heart [22, 23]. Thus we would expect the less compliant fetal heart to demonstrate a higher LVEDP at the LVDP plateau rather than the lower LVEDP we have demonstrated. Other explanations may include (1) differences between fetal and mature myocardium as discussed above, (2) differences in fetal and mature coronary circulation, or (3) differences in inotropic state.

The isolated adult heart has been used widely to study cardiac metabolism and mechanics [21]. Our model employs the fetal lamb heart in an isolated isovolumetrically contracting model employing completely extracorporeal circuitry and autologous fetal blood. With this model, we were able to study a stable fetal working heart, controlling variables of cardiac mechanics such as heart rate, afterload, coronary perfusion pressure, and inotropic state while evaluating the LV volume-pressure relationship.

In summary, we have used a beating isolated heart model to study fetal cardiac mechanics. We have demonstrated in this study that the fetal lamb heart is capable of a significant systolic pressure-volume relationship. This is demonstrated by the Starling curves consistently produced, and is confirmed by the regression analysis that demonstrates a clear relationship between preload (LV volume in this study) and LVDP. The Starling curve consistently peaks at a lower end-diastolic pressure than has been reported for mature or adult hearts. However, the mechanism to explain this is not apparent and is beyond the scope of this study. The fetal heart may have difficulty recruiting any preload reserve because it probably functions at rest near the peak of the curve.

Although preload reserve is demonstrated by this study, we are unable to compare the relative degree of reserve of the fetal heart and mature hearts. It is difficult to develop volume controls to compare cardiac function in small immature and large mature-size hearts. Although such control methods have been suggested [24], they remain suspect.

This study confirms that preload reserve is present in the fetal heart. Judicious manipulation of the preload to affect cardiac output would seem appropriate in the management of fetuses and immature neonates.

Surgical Management and Radiological Characteristics of Bronchogenic Cysts

Hon-Chi Suen, MBBS, Douglas J. Mathisen, MD, Hermes C. Grillo, MD, Johanne LeBlanc, MD, Theresa C. McLoud, MD, Ashby C. Moncure, MD, and Alan D. Hilgenberg, MD

General Thoracic Surgical Unit and Department of Radiology, Massachusetts General Hospital, and Departments of Surgery and Radiology, Harvard Medical School, Boston, Massachusetts

Forty-two patients with bronchogenic cysts were treated over a 30-year period (1962 to 1991). The location was mediastinal in 37 and intrapulmonary in 5. Cysts were symptomatic in 21 patients (50%) and complications occurred in 11 (26%). The complications included infection in 5 patients, hemorrhage into the cyst in 2 patients, dysphagia due to esophageal compression in 2, adenocarcinoma arising from a bronchogenic cyst in an 8½-year-old girl, and an esophagobronchopleurocutaneous fistula as a result of previous incomplete resection in 1 patient. Magnetic resonance imaging has been found to provide specific diagnostic information about broncho-

genic cysts. All but 2 patients were treated with complete excision. One patient was managed by observation and another had drainage of the cyst by mediastinoscopy. Complications of treatment occurred in only 2 patients. One had a minor wound infection and the other had *Clostridium difficile* enterocolitis. Only 4 patients were lost to follow-up. No late complication or recurrence developed in those patients having complete excision. We recommend complete excision in most instances to confirm the diagnosis, relieve symptoms, and prevent complications.

(*Ann Thorac Surg* 1993;55:476-81)

Bronchogenic cysts are unusual congenital anomalies of lung development arising as a result of a group of cells that break off from the developing lung bud and differentiate on their own. They are usually found in the mediastinum around the tracheobronchial tree or in the pulmonary parenchyma. This apparently benign condition, however, can produce a variety of symptoms and complications. Bronchogenic cysts can present a diagnostic dilemma as well. The use of computed tomography, magnetic resonance imaging, and ultrasonography can differentiate these cystic lesions from other mediastinal tumors.

Material and Methods

Over a 30-year period (1962 to 1991), all patients with bronchogenic cysts managed at the Massachusetts General Hospital were reviewed. The medical records and radiographs of 42 patients were studied. Criteria for inclusion include histologically confirmed bronchogenic cysts ($n = 37$), mediastinal cysts of undetermined origin but strongly believed to be bronchogenic cysts because of the typical location and behavior ($n = 3$), and clinically diagnosed bronchogenic cysts with no specimen submitted for histological study ($n = 2$). Follow-up was obtained from patient contact or office records.

Results

Age and Sex

There were 16 male and 26 female patients with a male to female ratio of 1 to 1.63. The age range was 8 to 62 years with a mean age of 34.8 years.

Symptoms

Symptoms were present in 21 patients (50%). Pain was the most common symptom, and it occurred in 10 patients (24%). The pain was located substernally in 6 and over the lateral chest in 2. One patient had a ruptured infected cyst and presented with right upper quadrant abdominal pain associated with lateral chest and shoulder pain. Another patient had a cyst on the anterolateral aspect of the thoracic vertebral bodies and presented with pain between the scapulae. Other symptoms included cough in 7 patients (17%), fever in 4 (10%), dysphagia in 2 (5%), purulent sputum in 2 (5%), hemoptysis in 1 (2%), and mild shortness of breath in 1 (2%). Several patients had more than 1 symptom.

Location

There were 37 mediastinal and 5 intrapulmonary bronchogenic cysts. The location of the mediastinal bronchogenic cysts was classified according to Maier [1]. Carinal and paratracheal locations were the most common (9 each). Paraesophageal was the next most common (8 patients), followed by hilar (5 patients). There were 6 pathologically confirmed bronchogenic cysts located in unconventional locations: 2 in the anterosuperior mediastinum, of which 1 was actually inside the thymus gland; 1 intrapericardial;

Fig 1. Bronchogenic cyst of the middle lobe showing homogeneous water density on a plain chest radiograph.

1 on the diaphragm; and 1 on the anterolateral surface of the thoracic vertebral bodies. One left hilar bronchogenic cyst was associated with a congenital defect of the adjacent pericardium. Our most recent patient had bilateral bronchogenic cysts as shown on chest radiograph, computed tomogram, and magnetic resonance imaging. The patient will undergo staged removal of the cysts, with the right-sided lesion having already been removed through a right thoracotomy. The lesions were thought to be inaccessible through median sternotomy. The intrapulmonary bronchogenic cysts did not show a predilection for any lobe. Two were in the right lower lobe and one each in the right middle, left upper, and left lower lobe.

Imaging

Standard chest radiographs identified the bronchogenic cysts in 37 patients (88%). The 5 not seen were all in the subcarinal position. Of those seen on standard radiographs, most presented as homogeneous water density shadows (Fig 1), whereas 2 patients had air-fluid levels (Fig 2). These 2 patients both had intrapulmonary lesions.

Barium swallow was performed in 14 patients and showed slight indentation of the esophageal image in 10 (71%).

Computed tomography was performed in 18 patients. The radiographic characteristics were those of a round, well circumscribed, unilocular or multilocular mass (Fig 3) with density ranging from water density (0 to 20 Hounsfield units [HU]) to as high as 91 HU. Occasionally computed tomography showed an air-filled cyst (Fig 4).

Magnetic resonance imaging was performed in 6 patients. In 1 of them, the cyst showed low signal intensity in T1-weighted images and bright signal intensity in T2-weighted images, indicating it was of low specific gravity and mainly serous. The other 5 cysts showed high signal intensity on both T1- and T2-weighted images (Figs 5, 6). This was due to the presence of a large amount of proteinaceous material or blood. The high signal intensity

Fig 2. Bronchogenic cyst of the left lower lobe with bronchial communication. The cyst is air filled and shows an air-fluid level.

on T1-weighted images was not attributable to fat because this differentiation was made by comparison with a corresponding computed tomogram.

Ultrasonography was performed in 2 patients. The bronchogenic cyst in 1 was in the subcarinal location, whereas the other was in the retrocardiac paraesophageal region. In both patients, an anechoic lesion was found and confirmed the cystic nature of the mass.

Endoscopic Findings

Results of bronchoscopy were available in 26 patients. Abnormalities were found in 9 patients. Abnormalities

Fig 3. Unilocular homogeneous fluid-filled bronchogenic cyst at the right paratracheal region.

Fig 4. Multilocular air-filled bronchogenic cyst of the left lower lobe.

were predominantly related to extrinsic compression of the tracheobronchial tree by the bronchogenic cysts. Blood-tinged material was seen coming from the middle and lower lobes in 1 patient with infected cyst, and 1 patient had bronchoscopic evidence of direct communication to the bronchus intermedius from a cyst that had previously been incompletely excised.

Needle Aspiration Biopsy

Needle aspiration biopsy was performed in 2 patients. In 1 patient, a small amount of material with red blood cells and lymphocytes was found. There were also rare intracellular acid-fast-positive round bodies of uncertain significance. In the other patient, inflammatory cells, debris, mesothelial cells, histiocytes, and lymphocytes were

Fig 5. Coronal T1-weighted image showing a right prevertebral bronchogenic cyst with high signal intensity consistent with high protein content.

Fig 6. Axial T2-weighted image of the same bronchogenic cyst as in Figure 5 showing it exhibits bright signal intensity.

found. Needle biopsy was not thought to be helpful in establishing the diagnosis in these 2 patients.

Diagnosis

Preoperative diagnosis was accurately made in only 17 patients (41%). With the present new imaging techniques, accuracy was much higher in patients treated recently.

Complications

Complications of bronchogenic cysts occurred in 11 patients (26%). Esophageal compression resulting in dysphagia occurred in 2 patients. Dysphagia was transient in 1 but lasted for 1 year before resection in the other. Dysphagia in both was due to subcarinal bronchogenic cysts. Hemorrhage into the cyst occurred in 2 patients.

Bronchogenic cysts became infected in 5 patients. An infected paraesophageal bronchogenic cyst ruptured and caused pleuritis and partial collapse of the right lower lobe in 1 patient. Postobstructive pneumonia developed in 1 patient, and 2 patients with intrapulmonary bronchogenic cysts presented with purulent sputum. *Aspergillus fumigatus* was cultured from 1 of these patients. The fifth patient with infection was entirely asymptomatic. A left upper lobe intrapulmonary bronchogenic cyst was discovered on a routine chest radiograph. A left apicoposterior segmentectomy was performed to remove the cyst. Pathological examination showed a bronchogenic cyst with chronic inflammation of cyst lining with focal erosion and focal granulomas. Special stain did not reveal acid-fast bacilli or fungi, but a culture of a specimen of the cyst grew *Mycobacterium tuberculosis*. This patient received antituberculous treatment.

An 8½-year-old girl presented with a mass in the subcarinal region with near-total obstruction of the distal trachea and right main bronchus. A 2 × 3 × 3-cm mass adherent to the carina was removed, and the defect in the membranous portion of the carina was closed primarily. Pathological examination showed that the mass was an adenocarcinoma arising from a bronchogenic cyst. The patient was referred for carinal resection and reconstruction. A successful operation was performed, and pathological examination showed no residual cancer.

A 24-year-old patient presented with a fistula between a residual bronchogenic cyst and the bronchus intermedius. He had initially undergone an incomplete excision of a subcarinal bronchogenic cyst in another institution. One and a half years later, the patient presented with an esophagobronchopleurocutaneous fistula and mediastinitis. Several operations failed to correct the problem. The patient was referred to us and underwent successful resection of the residual cyst and closure of the bronchial fistula.

Treatment

Only 1 patient in our series was followed up without intervention because of multiple medical problems. The patient was asymptomatic and remained so for 12 years. One patient had evaluation of a large paratracheal mass with mediastinoscopy. A large fluid-filled cyst was entered, and 750 mL of brownish red fluid was removed. No further treatment was recommended because of other medical problems. The mass persisted in subsequent chest radiographs. Two patients underwent resection through a median sternotomy because a mediastinal tumor was suspected. The remaining patients underwent resection by either right ($n = 29$) or left ($n = 9$) thoracotomy. The patient who has bilateral bronchogenic cysts will undergo left thoracotomy to complete the removal of the left-sided component at a later date. In all but 3 mediastinal bronchogenic cysts, only the cyst itself was removed. The thymus gland was removed as well in 1 patient because the bronchogenic cyst was in the thymus gland. An ellipse of pericardium was removed in 2 patients because of adherence. In the patient who had a ruptured infected paraesophageal bronchogenic cyst, decortication and drainage of the empyema was performed. In 4 patients, the bronchogenic cysts were so adherent to the tracheobronchial tree that either the trachea or the main bronchi were entered during dissection, creating a small defect in the membranous wall. The defects in the airway were closed successfully without further complications. In all intrapulmonary cysts, pulmonary resection was required. Wedge excision ($n = 1$), segmentectomy ($n = 1$), and lobectomy ($n = 3$) were performed to enable complete removal of the bronchogenic cysts.

Morbidity and Mortality

Postoperative complications occurred in only 2 patients. A minor wound infection developed in 1 patient, and *Clostridium difficile* enterocolitis secondary to perioperative antibiotics developed in another. There was no operative mortality. Median hospital stay was 7.9 days (range, 2 to 23 days).

Pathological Findings

Specimens were available for pathological examination in 40 of the 42 patients reported. Typical histological features included a ciliated columnar epithelial lining and a connective tissue wall with or without cartilage in 37. Three of the specimens were cysts that did not show recognizable epithelium but were believed strongly by us to be bron-

chogenic cysts because of their typical location and behavior. The size of the bronchogenic cysts ranged from 2 to 12 cm in the maximum diameter, with an average of 5.3 cm. Noniatrogenic bronchial communication was found in 3 patients. Two of them had intrapulmonary cysts that showed a fluid level on standard radiographs, and the third had a subcarinal cyst with two tiny communications with the left main bronchus discovered during operation. Cysts were unilocular in 29 patients, multilocular in 7, and aggregates of cysts in 4. Evidence of either acute, chronic, or granulomatous inflammation was found in 7 patients. The content of the cysts showed a great variety of color and consistency.

Follow-up

Only 4 patients were lost to follow-up. Thirty-four patients were contacted personally, and follow-up information was obtained from the office records of 4 patients. There were no late complications and no instance of recurrence of the cyst. The follow-up period ranged from 1 month to 26 years (mean, 8.2 years).

Comment

The first report of a bronchogenic cyst was in 1859 by Meyer [2]. By 1952, only about 100 cases were reported in the literature. Since then, numerous reports have appeared. Bronchogenic cysts account for about 5% to 10% of mediastinal masses.

Bronchogenic cysts can be found in a great variety of locations. Most bronchogenic cysts originate in the mediastinum with a smaller percentage occurring in the lung parenchyma, as in our series. They can occur in many atypical locations ranging from the neck [3, 4] to intradural [5] to below the diaphragm [6, 7].

Although many bronchogenic cysts are benign and asymptomatic and represent incidental findings on radiograph, many complications including lethal ones have been reported. Infection is a common complication, especially in those cysts with bronchial communication. Tracheobronchial compression can occur in children because of the relatively soft tracheobronchial tree [8]. Pressure on the adjacent esophagus can result in dysphagia. Superior vena caval obstruction has been reported by several authors [9, 10]. Pressure on the heart can produce arrhythmia [11] or obstruction of the right ventricular infundibulum, main pulmonary artery [12], right pulmonary artery [13], or left pulmonary artery [14]. The cyst can rupture into the trachea [15], the pericardial cavity [16], or the pleural cavity as in 1 of our patients. Malignancy has been associated with bronchogenic cysts. The first report was by Moersch and Clagett [17] in 1947, in which they reported one adenocarcinoma in 36 bronchogenic cysts and one squamous cell carcinoma found in a ciliated cyst of indeterminate origin. In 1951 Behrend and Kravitz [18] described a sarcoma arising from a bronchogenic cyst. Prichard and associates [19] reported two adenocarcinomas from large peripheral lung cysts, one thought to be bronchogenic in origin.

The radiographic characteristics of bronchogenic cysts

have been well defined by others [20]. Intrapulmonary bronchogenic cysts are usually sharply defined, solitary, noncalcified, round or oval opacities confined to a single lobe, usually a lower lobe. The cysts change little in size over a long period of time. They can present as a homogeneous water density, as an air-filled cyst, or with an air-fluid level. The wall is usually very thin, measuring 1 to 2 mm, and fine septa may be seen crossing through the cyst. Mediastinal bronchogenic cysts are usually homogeneous, smooth, solitary, round or ovoid, noncalcified masses located in the middle, posterior, or superior mediastinum in close association with the trachea or major bronchi.

Computed tomography has proven to be helpful in the diagnosis of bronchogenic cysts and often demonstrates a cyst not visible by conventional radiographic techniques. Computed tomography is also very useful in demonstrating the relation of bronchogenic cysts to other mediastinal structures. The computed tomographic density of bronchogenic cysts can vary from typical water density (0 to 20 HU) to high density (89 to 99 HU), as illustrated in 1 of our patients. Higher computed tomographic numbers represent increased calcium content, anthracotic pigment, blood, or greater protein content of the fluid [21]. Computed tomographic density up to 130 HU has been reported in adult patients [22].

Magnetic resonance imaging may provide specific diagnostic confirmation in regard to bronchogenic cysts. The magnetic resonance appearance is dependent on the cyst's content, specifically the presence and amount of mucus or other proteinaceous material. If the fluid within a bronchogenic cyst is of low specific gravity and mainly serous (a spring water cyst), it will be of very low signal intensity on T1-weighted images and of very bright signal intensity on T2-weighted images. However, many bronchogenic cysts may contain large amounts of proteinaceous material. Such cysts have a characteristic appearance with high signal intensity on T1-weighted images. This appearance must be differentiated from lesions that contain fat, which also has bright signal intensity on T1. However, that differentiation can easily be made by comparison with a corresponding computed tomogram. Fatty lesions will be of low attenuation on computed tomograms. Such bronchogenic cysts will have slightly diminished signal intensity on T2-weighted images, and they will often display either fluid/fluid levels or areas of heterogeneity. We believe that magnetic resonance imaging can diagnose bronchogenic cysts accurately and is indicated to confirm the diagnosis, especially when the surgeon does not want to operate on the patient. When the cyst is in a suitable location, ultrasound can be a useful tool to demonstrate the cystic nature of the lesion, as was done in 2 of our patients.

Percutaneous needle aspiration can be used for diagnostic purposes or even therapeutic purposes if thin fluid is present within the cyst. This technique for diagnosis was used only twice in our series and was not helpful in either case. Simple aspiration as a form of treatment is likely to have a high recurrence rate because the lining of the cyst is not obliterated.

Mediastinoscopy has been used to evaluate and treat bronchogenic cysts. Some authors have advocated removal of the cysts piecemeal with biopsy forceps through the mediastinoscope [23]. If the cyst wall remains intact, a high recurrence rate can be expected. Caution should be exercised in using this method for infected cysts.

We advocate complete excision in most cases. Often the diagnosis is in doubt and malignancy is suspected. Little doubt exists about the need to excise symptomatic cysts. We prefer to excise known asymptomatic bronchogenic cysts because of the risk of complications. The high rate of complications that we observed confirms the recent observations of St-Georges and associates [24]. In certain patients, observation is acceptable if the diagnosis is established and the patient is asymptomatic. Development of symptoms or a change in size warrants excision. If excision is undertaken, complete excision should be the goal. Incomplete excision will lead to a high recurrence rate and the potential for more serious complications as in our patient in whom an esophagobronchopleurocutaneous fistula developed. Any communication with the tracheobronchial tree should be carefully closed and buttressed with local, healthy tissue whenever possible. Intrapulmonary bronchogenic cysts should be excised because of the high incidence of secondary infection associated with them. Lung-sparing procedures compatible with complete excision should be done because of the benign nature of most of these cysts.

We thank Linda A. Lineback for helping with the follow-up of the patients.

De Vega's Semicircular Annuloplasty for Tricuspid Valve Regurgitation

Jeng Wei, MD, Chung-Yi Chang, MD, Fan-Yen Lee, MD, and Ween-Yuang Lai, MD

Divisions of Cardiovascular Surgery and Cardiology, Tri-Service General Hospital, National Defense Medical Center, Taipei, Taiwan, Republic of China

Moderate to severe functional tricuspid regurgitation was found in 26% of cardiac surgical patients with mitral or aortic valvular disease at Tri-Service General Hospital in Taiwan. Almost all patients were able to receive de Vega's annuloplasties. After a mean follow-up period of 20 months, none of the 63 patients had moderate or severe tricuspid regurgitation. There was no heart block or right atrial thrombosis; the single late death was not

related to the heart disease. De Vega's tricuspid annuloplasty is considered to be a safe, effective, and durable procedure in the treatment of functional tricuspid regurgitation. Compared with tricuspid valve replacement and other types of annuloplasty, the de Vega is the first choice here.

(*Ann Thorac Surg* 1993;55:482-5)

Tricuspid regurgitation (TR) may be present in 10% to 50% of patients with severe mitral stenosis or regurgitation [1, 2]. In a majority of patients, this condition is functional in nature, secondary to pulmonary hypertension and right ventricular dilatation [3, 4]. Spontaneous regression of functional TR after repair of the mitral lesion is in some cases impossible, and tricuspid valve annuloplasty (TVA) or even tricuspid valve replacement (TVR) is inevitable [1]. Tricuspid valve annuloplasty is a simple, safe, effective, and reliable surgical procedure for which there are several techniques. Although some surgeons prefer to do TVA with a Carpentier ring [5], the semicircular annuloplasty introduced by de Vega [6] is one of the simplest and easiest methods. Here, experience and mid-term results in this hospital, using de Vega's TVA in patients with functional TR, are described.

Material and Methods

Patients

Between January 1987 and May 1991, mitral or combined mitral and aortic valve operations were carried out in 176 patients, and de Vega's TVA was performed in 63 patients. Of the patients having de Vega's TVA, 43 were female and 20 were male, with an average age of 48.2 ± 12.9 (standard deviation) years (range, 12 to 74 years).

Preoperative diagnosis of TR was made by echocardiograms and was confirmed by finger palpation intraoperatively. Doppler echocardiography was performed before, and bimonthly after, operation to determine the severity of TR graded by the percent area of the regurgitant flow of the right atrium as follows: grade 1 = minimal flow, grade 2 = less than 20%, grade 3 = 20% to 40%, and grade 4 = more than 40%.

Indications for TVA were (1) TR of grade 3/4 or more as determined by right ventriculography, (2) TR of grade 3 or more as evaluated by Doppler echocardiography, or (3) moderate to severe TR as assessed by digital palpation through the right atrial appendage before the institution of cardiopulmonary bypass.

Concomitant procedures carried out at the time of tricuspid valve operation were mitral valve replacement in 34 patients, combined aortic and mitral valve replacement in 11 patients, aortic valve replacement in 1 patient, mitral valve commissurotomy in 2 patients, closure of atrial septal defect in 10 patients (including 1 patient with Holt-Oram's syndrome), and pulmonary valvotomy in 1 patient. Only 4 patients had simple TVA without other concomitant procedures.

The TR in all patients who underwent TVA was functional. Causes were mitral or aortic valve disease in 49 patients, atrial septal and pulmonary hypertension in 9 patients, pulmonary valve stenosis in 1 patient, arrhythmia-induced right ventricular dysplasia in 1 patient, hyperthyroidism in 1 patient, Holt-Oram's syndrome in 1 patient, and unknown in 1 patient.

Tricuspid valve replacement was performed in 22 patients during the same study period. Among these patients, 16 (73%) had organic change of the tricuspid valve: previous tricuspid valve replacement in 2 patients, subacute bacterial endocarditis of the tricuspid valve in 5 patients, Ebstein's anomaly in 1 patient, rheumatic tricuspid valve stenosis in 5 patients, and traumatic tricuspid valve regurgitation in 3 patients. Only 6 patients (27%) had functional TR: failed de Vega's annuloplasty in 4 patients, recurrent TR after annuloplasty in 1 patient, and TR caused by atrial septal defect and severe pulmonary hypertension in 1 patient.

Operative Technique

Under general anesthesia, a median sternotomy was done. The aorta, superior vena cava, and inferior vena

Fig 1. Suture techniques of de Vega's tricuspid valve annuloplasty: Two semicircular pursestring sutures, made with the same 2-0 polypropylene stitch, are started from the anteroseptal commissure and penetrate the annulus until the midportion of the coronary sinus. The two rows of sutures are parallel, but the sequences of penetration are alternative so that homogeneous narrowing of the annulus is achieved. (A = anterior leaflet; CS = coronary sinus; P = posterior leaflet; S = septal leaflet.)

cava were cannulated, and the patients were put on cardiopulmonary bypass. Moderate hypothermia and hemodilution techniques were employed. Before cardiopulmonary bypass, an average of 500 mL of autologous blood was collected for postoperative transfusion. The aorta was cross-clamped, and crystalloid cardioplegic solution was infused into the aortic root. Left-sided heart lesions were corrected first; then the right atrium was opened and the tricuspid valve was thoroughly examined. If there were no structural change on the leaflets, then TVA would be performed. A 2-0 polypropylene suture with Teflon felt was placed in the annulus, beginning at the commissure between the anterior and septal leaflets. The suture was continued along the tricuspid annulus, and ended at the coronary sinus to form a pursestring. The other arm of the suture was used to make a similar pursestring, but in an alternative sequence to bring the stitches in and out of the annulus (Fig 1). Penetration depth of the stitches was 3 to 5 mm. Sutures were then tied to narrow the tricuspid annulus. A 31-mm valve sizer was placed in the annulus during suture tying to achieve a proper size annulus. Two silver clips prevented the knots from loosening.

After TVA, cold saline solution was rapidly flushed into the right ventricle to test the competency of the tricuspid valve. If the tricuspid valve and the right ventricle could be distended with solution and without substantial leakage, the right atrium was closed. Substantial leakage of solution from the tricuspid valve was an indication to do a valvular replacement.

Follow-up

Patients were followed up, as outpatients, by Doppler echocardiography every 2 months. The mean follow-up period was 20.0 months with a range of 3 to 41 months.

Results

Incidence

The incidence of functional TR in patients who received mitral or combined mitral and aortic valve operations is 46 of 176 or 26%.

Immediate Successful Rate

Of the 67 patients who received de Vega's TVA, only 4 had serious leakage from the tricuspid valve during intraoperative saline flushing test; these finally received TVR. The other 63 patients performed well and had no serious TR detected by finger palpation after being taken off the cardiopulmonary bypass. Thus, the immediate rate of success of TVA during the operation was 94%. There was no operative mortality.

Follow-up Study

The preoperative severity of TR as assessed by Doppler echocardiography was grade 3 in 18 patients (29%) and grade 4 in 45 patients (71%). After a mean follow-up period of 20 months postoperatively, 17 patients (27%) had no TR, 42 patients (67%) had grade 1 TR, and 4 patients (6%) had grade 2 TR; no patient had grade 3 or grade 4 TR. Of those patients with grade 2 TR after the operation, none had residual left-sided heart lesion; their daily demand for diuretics was 20 to 40 mg of furosemide, and was not higher than that of other patients. Only 1 patient, whose TR was caused by arrhythmogenic right ventricular dysplasia, had persistent right heart failure after the operation. As to the functional status, 29 patients (46%) were in New York Heart Association functional class I, 31 (49%) were in functional class II, and 3 (5%) were in functional class III.

Mortality

There was no hospital mortality. One patient died of intracranial hemorrhage 2 months after the operation, possibly from a coumarin overdose. There has been no late death.

Complications

One patient had postoperative bleeding and was reopened for bleeding check. Another patient was reoperated on for paravalvular leakage from the prosthetic mitral valve. Two further patients suffered stroke during hospitalization. There was no conduction disorder either early or late after the operation.

Reoperation

No patient has had development of recurrent TR severe enough for reoperation during this study period.

Comment

Tricuspid regurgitation may be functional or organic. Functional TR is commonly secondary to left heart lesions, which lead to dilatation of the right ventricle and the tricuspid annulus; organic TR may be secondary to rheumatic fever, trauma, carcinoid syndrome, or subacute bacterial endocarditis. Although Braunwald, Ross, and Morrow [7] reported that secondary tricuspid regurgitation generally resolves after a successful mitral valve operation, other authors report different experiences [2]. Goldman and associates [8] reported that residual TR after mitral valve operations may significantly increase postoperative morbidity and mortality, and suggested detection

of TR by routine echocardiography. Boyd, Reed, and their colleagues [9, 10] reported that 22% to 30% of patients with mitral valve disease have associated TR. In this series, of the 176 patients who underwent mitral or combined mitral and aortic valve operations, 46 patients (26%) had concomitant moderate to severe TR. Thus the incidence here was similar to that in other series.

Of 48 patients who had left heart valvular diseases, 47 had either mitral or combined mitral and aortic valve lesions; only 1 patient had a single aortic valve lesion. This condition indicates that mitral valve lesion causes pulmonary hypertension and subsequent right ventricular dilatation and TR, whereas aortic valve lesion causes dilatation of the left ventricle and is less likely to cause TR.

The tricuspid valve is the largest valve in the heart, with an average area of 10.5 cm² and an average diameter of 36 ± 4.5 mm [11]. It has three leaflets: anterior (the largest), posterior, and septal. The anterior leaflet commonly attaches to a single major papillary muscle, whereas the posterior and septal leaflets generally directly attach to the right ventricular wall with chordae tendineae [11]. The conduction system penetrates the base of the septal leaflet; thus, this part of the annulus should not be sutured during annuloplasty. With right ventricular dilatation, the tricuspid annulus enlarges along the major portion of the attachment of the anterior leaflet, the posterior leaflet, and the lateral third of the septal leaflet. For this reason most annuloplasties shorten the annulus at the anterior and posterior leaflets [5].

The degree of functional TR is related to the following factors: (1) the severity of left-sided lesion, (2) the duration of the left-sided lesion, (3) the severity of pulmonary vascular resistance and pulmonary hypertension, and (4) the degree of right ventricular dilatation [11].

The optimal goal of the treatment of valvular insufficiency is reconstruction instead of replacement. Not all cases of mitral insufficiency, and few cases of aortic insufficiency, can be repaired. Functional tricuspid insufficiency, however, can be repaired in almost all cases. In this series, TVA was unsuccessful in only 4 of 67 patients.

All the complications related to valve prostheses may occur in TVR. Thrombosis of the mechanical prosthetic valve in the tricuspid position has varied between 4% and 30% [12-14]. Although bioprostheses have lower thrombogenicity in the tricuspid position, calcification and degeneration remain the chief problems [15, 16]. Another problem with TVR is the inequity between the prosthesis and the right ventricular cavity. The particular configuration of the right ventricle has been thought to be detrimental to the ideal functioning of a valve prosthesis. Complete heart block occasionally develops late after TVR, especially when a combined mitral valve replacement is performed. This association is undoubtedly related to the interposition of the atrioventricular node between the two replacement devices. Kirklin [17] reported that about 10% of patients receiving both tricuspid and mitral replacement require insertion of a pacemaker postoperatively because of heart block; up to 10 years postoperatively, the actuarial incidence is 25%. Present results show no heart block and thrombosis in patients

who received TVA. For these reasons, TVA is preferable to TVR in the treatment of functional TR.

However, TVA is unsuitable for organic TR. In organic TR, the tricuspid valve is destroyed and has to be replaced because deformed tricuspid valve leaflets cannot be corrected by simply narrowing the annulus.

In this series, 10 patients with atrial septal defect (including 1 patient with Holt-Oram's syndrome) had development of TR and needed TVA. The mechanism of TR might be the same as functional TR caused by mitral valve disease, ie, the dilatation of the right ventricle. Most of these patients were adults with pulmonary hypertension, which might have been responsible for right ventricular dilatation.

Two other methods of annuloplasty are commonly used for TVA: (1) Kay or Wooler [9] TVA, which is bicuspidalization of the tricuspid valve by making sutures to obliterate most of the posterior annulus, and (2) Carpentier [5] TVA, in which interrupted sutures are made from the tricuspid valve annulus to a ring with a C-shaped configuration open at the area of the penetrating bundle of His. Grondin and associates [18] reported that the Carpentier's and de Vega's annuloplasties appear superior to Kay's bicuspidalization annuloplasty according to hemodynamic studies after 11 and 10 months. In contrast, Péterffy and colleagues [19] and Nakano and associates [20] reported that Kay's and de Vega's annuloplasties gave similar and good late results in about 70% of the patients. At this hospital, no comparison has been made of results of de Vega's annuloplasty with those from other techniques, but the data show that de Vega's annuloplasty resulted in nearly total satisfaction after a mean follow-up period of 20 months. In these 63 consecutive patients, the actuarial survival rate was 98.4%, and the actuarial rate of freedom from reoperation on the tricuspid valve was 0%. Almost no patient (93.7%) had even minimal TR during the follow-up, and no patient had grade 3 or more TR after operation. This early experience with de Vega's annuloplasty has shown that the sutures should be deep enough to hold the annular tissue strongly to avoid cutting through the tissue after the heart resumes the contraction. Another factor that might be related to good outcome in our patients is that narrowing of the TV annulus is more homogenous when the pursestring sutures are made in an alternative sequence.

We conclude that (1) de Vega's TVA is an effective, reliable, and durable technique in treatment of functional TR; (2) de Vega's TVA can be performed in almost all patients with functional TR; (3) de Vega's TVA seldom causes the heart block and thrombosis that commonly occur in TVR; (4) de Vega's TVA saves heart ischemic time and reduces operative risk; (5) de Vega's TVA needs no prostheses and is the least expensive way to treat functional TR; and (6) de Vega's TVA is the treatment of choice for functional TR.

We are grateful to Miss Ling-Feng Yang for recording echocardiograms and to Miss Jean Lee for her assistance in data collection and secretarial support.

INVITED COMMENTARY

This is a summary of results in 63 patients with moderate or severe tricuspid regurgitation that resulted from "functional" tricuspid annular dilatation, secondary to left-sided valvular heart disease. Interestingly, this was the most common cause in this series from the Republic of China, yet this is also the most common cause of tricuspid valve regurgitation in North America. Wei and associates stress that for this diagnosis the necessity of replacing the tricuspid valve is virtually nil with current day techniques, a concept I totally endorse. They have used the de Vega semicircular annuloplasty, whereas we have adopted a variation of this technique using only a posterior de Vega-type annuloplasty. Pathophysiologic studies from a number of centers have indicated that the primary site of the dilatation of tricuspid annulus is the posterior aspect, which is more or less the free margin of the tricuspid valve. Thus, an annuloplasty beginning at approximately 12 o'clock and extending to approximately 6 o'clock, tied down over an obturator in the valve orifice, will suffice for almost all patients with moderate tricuspid regurgitation.

For severe tricuspid regurgitation, however, I take a different tack than Wei and associates, and advise tricuspid ring annuloplasty. I think that the high recurrence rate of the de Vega-type extensive semicircular annulo-

plasty previously recorded has been in the massively dilated tricuspid annulus with severe signs of right-sided congestive failure, including hepatomegaly and ascites. In this clinical syndrome, the annular tension on the annuloplasty stitch may be enormous, and a high incidence of recurrence has been reported in massive tricuspid regurgitation. Here the rigid Carpentier ring or the flexible Duran ring gives more solidity to the repair and is strongly advised for the patient with massive tricuspid regurgitation. Wei and associates have done an excellent job in presenting the case for repair of the tricuspid regurgitation. With the standardization of tricuspid annuloplasty techniques, it is clear that this defect can be ameliorated in the vast majority of patients by reconstructive techniques using both the semicircular or other suture techniques as well as ring annuloplasty techniques in patients with severe hemodynamic compromise by tricuspid regurgitation.

Reoperative Coronary Artery Bypass Grafting Without Cardiopulmonary Bypass

William J. Fanning, MD, Gerard S. Kakos, MD, and Thomas E. Williams, Jr, MD, PhD

Divisions of Thoracic and Cardiovascular Surgery, Grant and Mount Carmel Medical Centers and The Ohio State University, Columbus, Ohio

Between June 1979 and January 1992, 46 men and 13 women aged 35 to 81 years (mean, 58 years) underwent reoperative coronary artery bypass grafting without cardiopulmonary bypass. Isolated reoperative circumflex bypass was performed through a left thoracotomy, and reoperative bypass to the right coronary artery and left anterior descending coronary systems was through a median sternotomy. Complete revascularization was the goal in all patients. Saphenous vein grafts were placed to the right coronary artery (n = 21), circumflex artery (n = 11), and left anterior descending artery (n = 24), and 14 internal thoracic artery to left anterior descending artery bypass grafts were performed. The overall mortality rate was 3.4% (2 deaths). Postoperative morbidity included

myocardial infarction in 1 patient and pleuropulmonary complications in 6. No patient was reexplored for hemorrhage, and 19 patients required no blood products. Twenty patients underwent repeat coronary angiography, and 18 of 20 grafts placed without cardiopulmonary bypass were patent. At a mean follow-up interval of 42.2 months 35 of 50 evaluable patients were in functional class I or II. In selected patients, reoperative coronary artery bypass grafting can be performed without cardiopulmonary bypass with a low perioperative morbidity and mortality rate, satisfactory graft patency rates, and good long-term symptomatic improvement.

(*Ann Thorac Surg* 1993;55:486-9)

A recent survey of open heart surgery in New York State demonstrated that almost 10% of all adult cardiac surgical procedures were reoperations, with the majority being myocardial revascularization [1]. As the overall experience with reoperative coronary artery bypass grafting (CABG) has increased, alternative strategies have evolved in an attempt to lower the operative risks, which exceed those of initial revascularization [2]. These include different techniques for sternal reentry, strict avoidance of graft manipulation to minimize the risk of graft atheroembolism, and modifications in the method of

For editorial comment, see page 329.

myocardial protection depending on the status of the native coronary circulation and patency of vein or internal thoracic artery (ITA) grafts. As an alternative method of "myocardial protection" and to obviate the inherent risks of cardiopulmonary bypass, we have performed reoperative CABG without cardiopulmonary bypass (CPB) in a carefully selected group of patients. This report outlines that experience.

Material and Methods

Patients

From June 1979 to January 1992, 59 patients underwent reoperative CABG without CPB. Over the same time frame 540 patients underwent reoperative CABG with

CPB. Elective operations were performed in 44 patients with chronic angina refractory to medical therapy. Nineteen patients in this group had previously undergone one to six prior coronary angioplasty procedures. Eleven patients were operated on urgently because of unstable angina requiring intravenous nitroglycerin and heparin, and 4 patients were surgical emergencies because of coronary occlusion after a failed coronary angioplasty.

The group of patients consisted of 46 men and 13 women aged 35 to 81 years (mean age, 58 years). Twelve patients were older than 70 years, including 2 patients aged 81 years. Eleven patients had suffered a prior myocardial infarction. Left ventricular ejection fraction in this group ranged from 0.16 to 0.75 (mean, 0.48). Fifty-six patients underwent their first and 3 their second reoperation for myocardial revascularization.

This technique was used in two situations: (1) Patients in whom target vessels were limited to the right coronary artery (RCA) and left anterior descending (LAD) coronary systems with either an undiseased or nongraftable circumflex (Cx) system or patent and nondiseased Cx grafts (n = 48) were reoperated on through a median sternotomy. (2) Patients in whom target vessels were limited to the circumflex system and the RCA and LAD grafts were angiographically normal (n = 11) were operated on through a left thoracotomy. Complete myocardial revascularization was the goal in all patients. Vein grafts were not routinely replaced if they were angiographically normal.

Forty-eight patients underwent single-vessel CABG including single aortocoronary vein grafts to the RCA (n = 15), LAD (n = 12), and Cx (n = 11) and 10 left ITA to LAD

bypass grafts. Eleven patients underwent two-vessel bypass with distal vein graft anastomoses performed to the RCA ($n = 6$), LAD ($n = 7$), and left anterior diagonal ($n = 5$), three left ITA to LAD bypass grafts, and 1 right ITA to LAD bypass graft.

Technique

All patients were monitored with radial arterial, central venous, and pulmonary arterial catheters. In the 48 patients reoperated on through a median sternotomy, standard techniques were employed for sternal reentry. The heart and ascending aorta were dissected free of adhesions to the extent required for satisfactory exposure. When appropriate, a second surgical team harvested an appropriate length of saphenous vein. When the ITA was to be used, it was prepared after the lysis of adhesions. The patient was systemically heparinized with 100 U/kg of sodium heparin, and the proximal saphenous vein to aortic anastomosis was constructed with running 5 or 6-0 Prolene (Ethicon, Somerville, NJ) using partial aortic occlusion. The graft flow was assessed and its length tailored appropriately.

When the RCA was grafted, the acute margin of the heart was retracted with a stay suture placed in the epicardium. The distal RCA was dissected free at the chosen site of anastomosis and surrounded with fine silk traction sutures. A 7-mm longitudinal arteriotomy was made, and one or two stay sutures of 7-0 Prolene were placed at the midportion of the arteriotomy to facilitate exposure of the lumen of the RCA. The distal saphenous vein to RCA anastomosis was then made with running 6-0 or 7-0 Prolene. The graft was deaired and flow reestablished. The technical details for LAD or diagonal grafting were similar. Exposure was obtained by elevating the heart on a laparotomy pad, and the hemodynamic response was observed. Mild hypotension was easily corrected with volume or pressor administration, usually phenylephrine hydrochloride (Neosynephrine; Winthrop Consumer Products, New York, NY). Occasionally, use of the ITA retractor to elevate and laterally distract the left side of the chest proved beneficial.

Reoperative coronary artery bypass to the circumflex system was performed through a standard left anterolateral or posterolateral thoracotomy using a double-lumen endotracheal tube. The left lung was collapsed and the pericardium was opened anterior to the phrenic nerve. The proximal anastomosis was performed to the left subclavian artery, and the distal anastomosis to the appropriate Cx marginal branch was constructed using the technique described above. Interrupted sutures were occasionally employed at the toe of the distal anastomosis, especially if the artery was less than 2 mm in diameter. Standard closure of the median sternotomy or thoracotomy wound was employed using one or two chest tubes. Temporary pacing wires were employed as required. In general the decision to perform CABG without CPB was made based on the intraoperative inspection of the coronary artery size and location as well as the hemodynamic response to cardiac distraction.

Results

In this consecutive series there were two postoperative deaths (3.4%). The first was in a 73-year-old woman with known cerebrovascular disease and two prior strokes who underwent two-vessel bypass grafting to the LAD and diagonal coronary arteries. Her postoperative course was unremarkable until she suffered an extensive hemispheric stroke on the third postoperative day, which proved fatal. The second death occurred in a 71-year-old man with angina at rest requiring intravenous heparin and nitroglycerin that could not be weaned. His left ventricular ejection fraction was less than 0.20, with a left ventricular end-diastolic pressure in excess of 30 mm Hg. His native coronary circulation was occluded, and the only patent vein graft (to the LAD) had extensive graft atherosclerosis. This patient was referred for reoperation as a "salvage" procedure, and based on prior experience, it was thought that this technique was applicable. Intractable cardiac failure developed after sternotomy, and he was noted to have free-floating atheroembolic debris when the LAD was opened. Despite regrafting of the LAD and RCA, inotropic support, and intraaortic balloon pump support, he died of low cardiac output syndrome in the operating room caused by presumed vein graft atheroembolism. Possibly, this patient's outcome may have been different with more traditional methods of revascularization; however, because of his very poor ventricular function and the strong clinical suspicion of coronary atheroembolism, the situation was thought to be irretrievable and he was not placed on CPB. We fully recognize the potential criticism of this patient's management; however, in our experience there were no other patients in whom an attempt at CABG without CBP resulted in hemodynamic or rhythm disturbance requiring CPB to complete the procedure. No other patient in this series required intraaortic balloon pump support. Five patients required inotropic support in the postoperative period for a cardiac index less than $2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$, and these 5 patients were weaned off all inotropes in the first 24 postoperative hours. No patient required ventilatory support longer than 48 hours.

Pleural effusions requiring tube thoracostomy or thoracentesis occurred in 5 patients. One patient had a prolonged air leak for 10 days after emergent single-vessel bypass grafting to the Cx marginal through a left thoracotomy after a failed percutaneous transluminal coronary angioplasty. An acute inferior myocardial infarction occurred in a 52-year-old man 1 day after left ITA to LAD bypass grafting. This patient's RCA and Cx grafts were occluded, as was the native circulation, and neither was thought to be graftable. He made an uneventful recovery.

No patient required reoperation for hemorrhage. Nineteen patients required no blood products. The average blood requirement in the remaining 40 patients was 1.2 units per patient. The majority of operations were performed when the indications for blood transfusion were more liberal, and only 5 of the last 17 patients required blood postoperatively. There were no wound infections. Of the 57 survivors, 39 were discharged on or before the

seventh postoperative day and 18 between postoperative days 8 and 17.

Twenty patients underwent repeat left heart catheterization and coronary arteriography at intervals varying between 2 weeks and 108 months postoperatively (mean, 24 months) because of recurrent chest pain syndromes. Eighteen of 20 grafts placed without CPB bypass were patent, including all vein grafts to the diagonal (1), RCA (9), and LAD (4). Three of four left ITA to LAD grafts and one of two Cx grafts restudied were patent. The cause of the recurrent chest pain in the 2 patients with graft occlusion was obvious. In 2 additional patients there was new vein graft atherosclerosis in grafts that were angiographically normal and 4 and 6 years old at the time of CABG without CPB; this was presumably the cause of recurrent chest pain. The cause of the chest pain in the remaining 16 patients was never clearly defined, but resolved without specific therapy.

The 57 survivors were seen at 1-month follow-up and were clinically improved. Seven of 57 survivors were lost to long-term follow-up. In the remaining 50 patients, follow-up ranged from 1 month to 11 years (mean, 42.2 months). Thirty-five were in New York Heart Association functional class I or II. Four patients were in functional class III to IV, 3 with chronic congestive heart failure and 1 with disabling angina. Three patients underwent a second coronary reoperation, 1 because of occlusion of a left ITA to LAD graft placed without CPB and 2 because of vein graft atherosclerosis. Eight patients died during the follow-up interval, 4 of presumed cardiac causes.

Comment

Coronary artery bypass grafting was first conceived and performed on dogs by Alexis Carrel in 1910 [3]. Murray and associates [4] "rediscovered" the operation in 1954 but did not recognize Carrel's contributions. In 1962 Sabiston [5] performed the first aortocoronary bypass graft in a human using saphenous vein, and in 1966 Kolesov [6] reported left ITA to LAD bypass grafting. These early attempts at direct surgical coronary revascularization were all performed on a beating heart without CPB. In 1970, Favaloro and colleagues [7] presented the Cleveland Clinic's initial experience with CABG and fueled the precipitous increase in direct coronary artery surgery in this country. In their report they recommended full CPB for revascularization of the left coronary artery but observed that in most patients bypass of the RCA could be done safely without circulatory support. Although virtually every facet of the operation has undergone numerous technical modifications, ranging from the method of myocardial protection to the type of conduit used, the vast majority are performed with total CPB. Although perfusion techniques continue to improve, there is still the potential for substantial morbidity and mortality associated with CPB, especially with the prolonged pump runs often required with reoperative procedures. To obviate the hazards of CPB, several groups have reported CABG without CPB.

In 1975, Trapp and Bisarya [8] reported 63 patients in

whom CABG was performed without CPB. Their technique involved a cumbersome, but seemingly effective system of coronary artery perfusion proximal and distal to the anastomotic site. Their report included no short-term or long-term follow-up data. In the accompanying editorial, Ankeney [9] expressed cautious support based on a personal experience with the technique, although he stated the coronary perfusion technique of Trapp and Bisarya was unnecessary. He emphasized the need to document graft patency and the incidence of perioperative myocardial infarction using this technique before it could be considered comparable with surgical revascularization using CPB. Strangely, Ankeney never published his results.

Faro and associates [10] demonstrated the feasibility of reoperative revascularization of the Cx or LAD systems in 7 patients through a left thoracotomy without CPB. The results were generally favorable, with postoperative angiograms demonstrating graft patency in 4 of 5 patients. Archer and co-workers [11] reported an experience of 191 patients undergoing single-vessel CABG without CPB, of whom 15 had reoperations. They documented a low perioperative and late mortality rate as well as decreased blood requirements in patients operated on without CPB. Their perioperative myocardial infarction rate for LAD bypass was 18.7%, and for this reason they abandoned the technique for isolated LAD bypass but thought the technique proved particularly useful after failed angioplasty of the RCA.

Buffolo and associates [12] reported 160 patients undergoing primary CABG without CPB with an acceptable mortality of 3.1% and a myocardial infarction rate of 2.5%. Forty-one unselected patients underwent postoperative coronary arteriography, and 84% of grafts restudied were patent. Laborde and colleagues [13] reported 38 patients undergoing CABG without CPB, including 35 having left ITA to LAD bypass grafts. There were no operative deaths and no perioperative myocardial infarctions, but no follow-up arteriography was done.

Benetti and associates [14] recently published a 12-year experience using this technique in 700 patients. The percentage of patients operated on in this series without CPB increased over the time frame of the study and reached 84% of their total coronary bypass experience in 1989. They documented a low morbidity (4%) and mortality (1%) rate. Only 10% of the patients required blood products, and 91% of patients were extubated immediately postoperatively. Hospital costs were significantly reduced in this group [15]. Fifty-four patients underwent repeat coronary angiography within 1 month postoperatively. Vein graft and ITA patency rates were 93% and 87.5%, respectively.

It is unclear from Benetti and associates' [14] report what percentage of patients had multivessel coronary disease, specifically diseased circumflex branches. Although this report describes successful revascularization of the Cx, bypass of the posterolateral branches of the Cx is not possible through a median sternotomy using this technique. As suggested in an accompanying editorial [16], either this group had incomplete revascularization or

the patient population is clearly different from that seen in the United States.

Previous reports fail to mention the utility of this technique in selected patients requiring reoperative CABG. Reoperative CABG without CPB requires less operating time and a shorter postoperative hospital stay, which translates into a reduction in hospital costs. There were fewer bleeding complications with this technique as almost one third of patients required no blood products and no patient was reexplored for excessive mediastinal hemorrhage. Although construction of distal anastomoses on the beating heart is technically more demanding and requires a short period of coronary occlusion, the observed incidence of postoperative myocardial infarction was low (1.8%).

Contrary to other reports, we have not found observation of the hemodynamic response to coronary occlusion beneficial in predicting the ability to perform a satisfactory and safe distal anastomosis. Experience with percutaneous transluminal coronary angioplasty has shown that most patients can safely tolerate brief periods of coronary occlusion. The factors that determined the ability to safely perform a technically satisfactory distal anastomosis were a coronary artery diameter at the anastomotic site of 2 mm or greater and satisfactory hemodynamics with the cardiac retraction required for exposure. Given these limitations, the technique has proved useful in selected patients requiring isolated reoperative revascularization of the RCA, Cx, and LAD using vein grafts. Hemodynamic intolerance to coronary manipulation required for grafting of the posterior descending branch of the RCA usually mandates CPB and obviates consideration of the technique. We avoid this technique when grafting a small LAD with a small ITA. Although the patients who underwent repeat coronary angiography were a select group biased toward those with recurrent symptoms, graft patency rates (90%) were comparable with reported patency rates for grafts placed using standard techniques with CPB and cardioplegic arrest.

Despite certain technical limitations, this method has proved quite useful in several situations deserving further mention. Three patients underwent successful emergent reoperative revascularization to a dominant Cx system through a left thoracotomy after a failed percutaneous transluminal coronary angioplasty. In one of these patients a standard reoperative approach through a median sternotomy would have potentially jeopardized a patent in situ right ITA to LAD graft. This approach greatly lessened that risk. In 2 other patients a left thoracotomy approach for isolated Cx repeat revascularization proved safe and expedient: 1 patient with a prior mitral valve replacement and patent grafts to the RCA and LAD and a second patient with unstable angina, a left ventricular ejection fraction of 0.16, and a prior history of a radical mediastinal tumor resection with subsequent mediastinal irradiation. Other situations where this technique proved beneficial included reoperation on a patient of the Jehovah's Witness faith and 1 patient with a prior cerebrovascular accident and a heavily diseased and calcified ascend-

ing aorta where left ITA to LAD grafting without CPB served as yet another "no touch" technique to minimize the risk of stroke [17].

Modifications in all aspects of the coronary reoperation will continue to evolve as surgeons are confronted by an ever-increasing number of patients requiring reoperative revascularization. Reoperative CABG without CPB is yet another technique that allows the operation to be tailored to the needs of the individual patient. It should be emphasized that this technique is no panacea, but in highly selected patients reoperative CABG can be performed safely and effectively without CPB.

Pentoxifylline Decreases Cyclosporine-Induced Renal Endothelin Release and Vasoconstriction

Michel Carrier, MD, Louis P. Perrault, MD, François Tronc, MD,
Duncan J. Stewart, MD, and Conrad L. Pelletier, MD

Department of Surgery, Montreal Heart Institute, and Department of Medicine, Royal Victoria Hospital, Montreal, Quebec, Canada

Cyclosporine (CSA) causes an acute vasoconstriction of renal artery and a significant increase in renal endothelin release. Pentoxifylline, a vasodilator, has been suggested to prevent CSA toxicity. To study the effect of pentoxifylline treatment on CSA-related vasoconstriction and endothelin release, a model of renal autoperfusion in the dog was used. Oral pentoxifylline at the dose of 400 mg three times daily for 3 days was given to 15 dogs. Pure powder CSA (10 mg) was injected into the isolated renal artery perfused at constant flow; changes in perfusion pressure reflected variations in vascular resistance. In the pentoxifylline-treated group (15 dogs), the infusion of

CSA caused an average increase of 27 ± 8 mm Hg in renal perfusion pressure, compared with 60 ± 10 mm Hg in a control group of 8 untreated animals ($p \leq 0.05$). Plasma concentration of endothelin in the renal vein increased from an average of 1.2 ± 0.2 pg/mL before to 2.4 ± 0.5 pg/mL after CSA administration ($p \leq 0.05$) in the control group, whereas it did not change significantly in the pentoxifylline-treated group. Thus, oral pretreatment with pentoxifylline significantly decreased the renal vasoconstriction and endothelin release due to CSA administration.

(*Ann Thorac Surg* 1993;55:490-2)

Cyclosporine (CSA) is currently the drug of choice for immunosuppression after solid organ transplantation. Hypertension and renal failure are the two most common and severe complications due to CSA after transplantation. The precise mechanism of CSA vascular toxicity is not yet fully understood. However, it has been shown that CSA causes an acute vasoconstriction of renal arteries [1-3], which could be responsible, at least partly, for the CSA side effects observed in clinical transplantation. Several mechanisms have been suggested to explain the effects of CSA on the arterial wall, including an increase in endothelin release from the renal vessels [1] and stimulation of the adrenergic system [4]. The latter has also been found in clinical studies [5, 6]. Recently, Bianco and associates [7, 8] have suggested that oral administration of pentoxifylline, a potent vasodilator, in patients undergoing bone marrow transplantation could significantly decrease renal failure due to CSA.

The goal of the present study was to evaluate the effect of pretreatment with pentoxifylline on the renal arterial vasoconstriction response to CSA.

Material and Methods

The study was performed in 23 dogs weighing 20 to 33 kg, anesthetized with pentobarbital (30 mg/kg intravenously) and artificially ventilated at 10 to 12 cycles/min with a Harvard ventilator. After heparinization (3 mg/kg), the left iliac artery and the left renal artery and vein were isolated. A cannula was introduced retrograde into the

iliac artery and connected to a circuit tubing including a heat exchanger, an occlusive roller pump, and a depulsator. Autologous blood maintained at 37°C was pumped at constant flow into the isolated renal artery after cannulation and proximal ligation of the artery at the origin from the aorta. The ipsilateral renal vein was cannulated for renal blood sampling.

The perfusion flow of the left renal artery was adjusted by controlling the pump speed at the beginning of the experiment to obtain a mean renal perfusion pressure equal to the mean aortic pressure. Changes in renal perfusion pressure therefore reflected changes in renal arterial resistance. Perfusion pressure was measured from the arterial line just proximal to the renal inflow cannula.

Arterial blood samples were obtained regularly throughout the experiment for blood pH, oxygen tension, and carbon dioxide tension measurements. Blood pH was maintained between 7.3 and 7.4 by ventilation adjustment and bicarbonate infusion as needed.

Drugs were infused directly into the renal inflow, proximal to the insertion of the renal artery cannula and to the site of perfusion pressure monitoring. Drugs were injected over a period of 10 minutes, and changes in perfusion pressure were recorded throughout the period of infusion. Between injections, the renal perfusion pressure was allowed to return to the baseline mean aortic pressure for at least 10 minutes. Typically, perfusion pressure reached a plateau 5 to 9 minutes after the beginning of CSA infusion and persisted 5 minutes or more after the end of infusion. The plateau level was recorded as the maximal effect of the drug on renal perfusion pressure.

Nitroglycerin (5 mg) was administered at the beginning

and at the end of each experiment to test the reactivity of renal arteries. Autologous blood alone was also injected to test reactivity to the vehicle. Pure powder CSA (Sandoz Canada, Montreal, Canada) was dissolved into autologous blood (60 mL) and injected at the dose of 10 mg. At the end of each CSA infusion, renal venous blood samples were withdrawn for determinations of CSA serum level by the fluorescence polarization immunoassay technique [9].

A group of 15 dogs was treated with oral pentoxifylline (Trental; Hoechst Canada, Montreal, Canada) at the dose of 400 mg three times daily during 3 days before the experiment. The effect of CSA on renal vascular resistance was then studied according to the protocol described. Plasma concentration of endothelin was also measured in 9 of these dogs, from peripheral venous blood sampling before the pentoxifylline treatment was started and in the renal vein before and after administration of CSA during the experiment. Endothelin-1 plasma concentration was measured by radioimmunoassay according to a method previously described [1].

Another group of 8 dogs studied without pentoxifylline pretreatment served as the control group. Plasma concentration of endothelin was measured in renal venous blood before and after CSA injection in this group.

The data are presented as mean changes in renal perfusion pressure, standard error of the mean, and 95% confidence interval (CI). Changes in perfusion pressure were analyzed by Student's paired and unpaired *t* test, and changes in endothelin levels were analyzed by Student's paired *t* test and by analysis of variance. The level of statistical significance was established at 95%. All animals were treated in accordance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Results

In the group of 15 dogs pretreated with oral pentoxifylline, nitroglycerin injection caused an average decrease of 44 ± 7 mm Hg (95% CI, 29–59 mm Hg; $p \leq 0.05$) in renal perfusion pressure, indicating good vascular reactivity.

Fig 1. Plasma levels of endothelin before pentoxifylline pretreatment, before and after injection of 10 mg of cyclosporine (CSA) in dogs. No changes in endothelin concentration were found (not significant by analysis of variance).

Fig 2. Increases in renal perfusion pressure with injection of 10 mg of cyclosporine in the pentoxifylline-pretreated group ($n = 15$) and the control group ($n = 8$). The difference in pressure increase is significant ($p \leq 0.05$).

Basal perfusion pressure averaged 123 ± 6 mm Hg before and 78 ± 5 mm Hg after nitroglycerin injection. Infusion of 60 mL of autologous blood did not cause any significant changes in perfusion pressure (7 ± 4 mm Hg).

Infusion of 10 mg of CSA caused an average increase of 27 ± 8 mm Hg (95% CI, 10–44 mm Hg; $p \leq 0.05$) in renal perfusion pressure from 105 ± 5 mm Hg to 132 ± 11 mm Hg with CSA serum levels averaging 360 ± 116 nmol/L at the end of injection. The plasma concentration of endothelin averaged 0.9 ± 0.2 pg/mL before pentoxifylline pretreatment, 0.7 ± 0.1 pg/mL immediately before CSA injection, and 1.3 ± 0.4 pg/mL after injection of CSA, differences that were not significant (Fig 1).

In the control group (8 dogs), nitroglycerin injection caused an average decrease of 61 ± 5 mm Hg (95% CI, 50–73 mm Hg; $p \leq 0.05$) in renal perfusion pressure. Injection of 10 mg of CSA caused an average increase of 60 ± 10 mm Hg (95% CI, 36–84 mm Hg; $p \leq 0.05$) in renal perfusion pressure, from 93 ± 5 mm Hg to 152 ± 10 mm Hg. The difference in the response of the control dogs from that of the pentoxifylline-pretreated group was statistically significant (Fig 2). The serum levels of CSA averaged 603 ± 161 nmol/L at the end of CSA injection, a nonsignificant difference from the pretreated group. The plasma concentration of endothelin in the renal vein averaged 1.2 ± 0.2 pg/mL before and 2.4 ± 0.5 pg/mL after CSA administration, a significant increase in release ($p \leq 0.05$) (Fig 3).

Comment

Clinical and experimental studies have shown that CSA causes a significant increase in renal arterial resistance at serum levels within the therapeutic range used in clinical transplantation [1–3]. Infusion of CSA has also been shown to increase significantly the renal release of endothelin [1], a potent endothelium-dependent vasoconstrictor peptide released in the renal vessels [1, 4, 10–12]. In vitro, CSA stimulates the secretion of endothelin by renal tubular and endothelial cells [13, 14]. Marked increases in plasma concentration of endothelin have been found in a

Fig 3. Plasma concentrations of endothelin before and after injection of 10 mg of cyclosporine (CSA) in the control group (8 dogs). A significant increase in endothelin concentration was obtained with CSA injection ($p \leq 0.05$).

small group of patients after liver transplantation [15]. These pieces of evidence suggest that CSA increases the endothelin release from renal endothelial cells, and that the resulting vasoconstrictive effect may play a key role in CSA nephrotoxicity and hypertension.

Pentoxifylline, a xanthine derivative with multiple effects on circulating blood cells, also exerts a potent vasodilator effect by increasing the intracellular level of adenosine 3',5'-cyclic monophosphate and by preventing the production and the effect of thromboxanes [16, 17]. In experimental studies, pentoxifylline was shown to prevent the hypoxia-related changes in renal function of transplanted kidneys [18], improve the clinical course and survival of acute renal failure [19], and reduce cyclosporin-induced nephrotoxicity in the rat [20].

In a recent clinical nonrandomized study, Bianco and associates [7] found that pentoxifylline could prevent cyclosporin toxicity in bone marrow transplant patients, as a significant decrease in the incidence of renal failure among patients treated with pentoxifylline was observed.

The results of the present study support the hypothesis of Bianco and associates. Oral pretreatment with pentoxifylline resulted in a decrease in renal vasoconstriction caused by CSA in a model of renal autoperfusion in the dog. Pentoxifylline pretreatment also prevented the increase in renal endothelin release caused by CSA, suggesting that the preventive action of pentoxifylline on CSA-induced changes in renal vascular resistance could be related to the latter mechanism. Serum levels of CSA were higher in the control group of animals; the difference could result from an incomplete dilution of CSA in the autologous blood or from an interaction between the two drugs. Further studies will clarify this aspect.

In conclusion, oral pretreatment with pentoxifylline prevents, at least partly, the renal vasoconstriction caused by CSA, and this effect may be due to inhibition of endothelin release, which therefore could be responsible for renal toxicity of CSA. Clinical studies will be needed to confirm the preventive effect of pentoxifylline on CSA-related nephrotoxicity. Oral pentoxifylline administered to transplant patients with CSA could become an approach to prevent the renal vascular toxicity of CSA.

This study was supported, in part, by the Medical Research Council of Canada (grant No. MT-11689). Michel Carrier is a scholar of the Fonds de la Recherche en Santé du Québec.

Dynamic Cardiomyoplasty in Chronic Left Ventricular Failure: An Experimental Model

Russell W. J. Millner, FRCS, Mark Burrows, MSCT, Ian Pearson, ALAT, and John R. Pepper, FRCS

Department of Cardiothoracic Surgery, St. George's Hospital, London, United Kingdom

Dynamic cardiomyoplasty continues to attract interest as a therapeutic option in the management of heart failure. In a large animal model of ischemic heart failure, we have compared dynamic cardiomyoplasty with both adynamic cardiomyoplasty and a control group. Heart failure was induced by coronary artery ligation in sheep, and under the same anesthetic dynamic cardiomyoplasty ($n = 5$), adynamic cardiomyoplasty ($n = 4$), or no further procedure was performed ($n = 5$). After recovery the animals were housed for a further 3 months. The dynamic cardiomyoplasty underwent a recognized muscle transformation protocol during this period. At terminal studies, the animals were hemodynamically assessed, both under baseline conditions and after colloid volume loading. The data at baseline were compared with unpaired t tests, and the function curves created by volume

loading were compared by analysis of variance. Although the changes at baseline were small, there were highly significant improvements in the function curves in the dynamic cardiomyoplasty group when the stimulators were turned on compared with stimulators off ($p = 0.005$ for cardiac output; $p = 0.035$ for left ventricular end-diastolic pressure; $p = 0.002$ for pulmonary artery capillary wedge pressure; $p = 0.004$ for stroke volume; and $p = 0.003$ for cardiac power). There were also significant improvements in indices of cardiac performance when the dynamic cardiomyoplasty group was compared with both the control and adynamic cardiomyoplasty groups. We conclude that there is experimental evidence that cardiomyoplasty augments cardiac function in a model of chronic left ventricular failure.

(*Ann Thorac Surg* 1993;55:493-501)

A major and continuing fault throughout the literature on experimental cardiomyoplasty is the lack of an effective and reliable chronic heart failure model. The result is that the majority of experimental studies published to date have been either acute studies using muscle that has not been previously transformed [1], or studies using muscle that has been transformed in situ and moved at the time of the operation with the animals studied acutely at that time. The final group of studies are those in which the operation has been performed and the animals allowed to recover and undergo a muscle transformation protocol with an acute type of study after this muscle transformation period [2].

These studies are criticized either on the grounds that the acutely operated muscle will produce more power with a much faster twitch than the transformed muscle [3], before it very rapidly fatigues, or that the acutely failing ventricle after administration of propranolol or similar agents is not representative of the clinical situation. Attempts to overcome these criticisms have focused on using chronically cardiotoxic agents such as the anthracycline antibiotic doxorubicin hydrochloride (Adriamycin; Adria Laboratories, Dublin, OH), the tricyclic antidepressant

imipramine, or long-term β -adrenoceptor blockade. Although doxorubicin produces an effect similar to a dilated cardiomyopathy, the toxicity and narrow "therapeutic" window have resulted in very high mortality rates in experimental cardiomyoplasty. The cost of these agents and the hematological monitoring that they need also inhibits their use.

Theoretical worries about the effects of long-term β -adrenoceptor blockade on skeletal muscle have also been raised in relation to dynamic cardiomyoplasty. There is experimental evidence that the training adaptations of skeletal muscle are impaired by long-term β -adrenoceptor blockade and that the effects depend on both the fiber type studied and the type of β -adrenoceptor antagonist used [4].

It was for these reasons that this study of dynamic cardiomyoplasty in an ischemic model of left ventricular (LV) failure was planned. We have previously shown that the sheep model of LV aneurysm produces hemodynamically significant LV failure [5].

Material and Methods

Three groups of animals were prepared. The first group were the animals with pure LV aneurysms (group 1). The second group of animals (group 2) underwent cardiomyoplasty after coronary ligation, but without the implantation of the cardiomyostimulator and leads (adynamic cardiomyoplasty). The third group (group 3) underwent cardiomyoplasty after coronary ligation with the simulta-

Accepted for publication June 12, 1992.

Mr Pepper's current address is The Royal Brompton and National Heart Hospital, Sydney St, London SW6, United Kingdom.

Address reprint requests to Mr Millner, Department of Cardiothoracic Surgery, The Middlesex Hospital, Mortimer St, London W1, United Kingdom.

neous implantation of the cardiomyostimulator and leads (dynamic cardiomyoplasty). In both groups 2 and 3, the cardiomyoplasty was performed at the same operation as coronary ligation, after the animals had hemodynamically stabilized. All group 3 animals underwent a standard muscle pacing protocol over 12 weeks, by the end of which they were receiving 5-V pulse trains of 240-ms duration, with a pulse frequency of 33 Hz and at a 1:1 relation with the cardiac R wave. This protocol has been described in detail elsewhere [6]. The other animals were housed for the same time before undergoing their terminal studies (groups 1 and 2).

Management of Experimental Animals

All animals received humane care in accordance with guidelines published by the National Society for Medical Research (Principles of Laboratory Animal Care) and by the National Institutes of Health ("Guide for Care and Use of Laboratory Animals"; NIH publication No. 85-23, revised 1985). The project was licensed and performed under the supervision of H. M. Inspector from the Home Office.

Operative Techniques

CREATION OF THE MYOCARDIAL INFARCT. Our anesthetic and operative management has been previously described [5], and creation of the myocardial infarct was based on a previously described method [7].

PREPARATION OF THE LATISSIMUS DORSI FLAP. In those animals in which a latissimus dorsi flap was raised, preparation of the latissimus dorsi flap followed immediately after the coronary artery ligation had been performed. The skin incision of the thoracotomy was extended further posteriorly and deepened with a scalpel through the superficial platysma muscle to the latissimus dorsi. Skin flaps were reflected both cranially and caudally until the whole of the muscle had been released over its subcutaneous aspect. Next the anterior border was completely mobilized, followed by the posterior border. The fibrous origin from the ribs was then divided and hemostasis on the chest wall and subcutaneous flaps secured. The muscle was then reflected anteriorly, allowing the common insertion with teres major to be divided with further mobilization of the latissimus dorsi flap. To avoid neurovascular damage, in this experimental model, the tendinous insertion onto the humerus was not divided.

The intercostal muscles over the third rib were divided and a 4-cm anterior arc of the third rib together with the periosteum was excised. The latissimus dorsi was then passed into the chest through this space. Pacing leads (SP5528; Medtronic Ltd, Maastricht, Holland) were attached (group 3 only) and the muscle passed over the front of the left ventricle. The muscle was secured in place by bringing the pericardial edges together over the front of the muscle. In addition the muscle was sewn to the diaphragmatic surface of the pericardium, ensuring stability during the earlier onset of the pacing protocol. In

group 3 animals the cardiomyostimulator (SP1005; Medtronic Ltd) was inserted into a subcutaneous pocket with the pacing leads being routed so that they did not lie directly under the incision.

Postoperative Study Protocol

Hemodynamic studies were performed at three points: before coronary artery ligation, 1 hour after coronary artery ligation, and 3 months after the initial operation. Three months after the initial operation the animals were reanesthetized using exactly the same protocol and reinstrumented in the same way as before.

Hemodynamic measurements were taken after the animals were anesthetized, ventilated, and fully instrumented, with their chests closed and under the same conditions as their preinfarction studies. Recordings were made at baseline and then after 500-mL boluses of colloid plasma expander (Gelofusine; Consolidated Chemicals Ltd, Wrexham, Wales). Measurements were made in group 3 with the pacemaker off after the animals had stabilized for 10 minutes, and repeated with the pacemaker on, using the parameters described above, after a further period of 10 minutes of stabilization. In groups 1 and 2 measurements were made at baseline and after 500-mL boluses of colloid plasma expander, with 10-minute stabilization periods after fluid loading and before recordings were made.

Once the hemodynamic study was completed, the animals were sacrificed under anesthesia for postmortem examination of their hearts.

Statistical Methods

The comparisons between the groups for preinfarction, postinfarction, and baseline terminal studies have been performed with unpaired two-tailed *t* tests. The initial comparisons between the groups for the function curves derived from volume loading at the terminal studies have been made with repeated-measures analysis of variance (ANOVA). Differences between groups at specific points on the volume loading curves were then inspected using paired or unpaired two-tailed *t* tests as appropriate for the groups under comparison.

Results

There were 6 animals suitable for study with adequate aneurysms in the dynamic cardiomyoplasty group (group 3), 5 animals suitable for study with adequate aneurysms in the adynamic cardiomyoplasty group (group 2), and 6 animals with aneurysms alone (group 1). Insurmountable technical problems during the terminal studies, while the animals were anesthetized and after monitoring lines had been inserted, resulted in loss of major elements of the data from 2 animals. These were 1 each from groups 1 and 3.

One animal from group 2 died very rapidly after the induction of anesthesia and while the monitoring lines were being inserted. Full resuscitative measures were attempted, but these were unsuccessful and it was not

Fig 1. Graph of cardiac output against volume of colloid transfused during the terminal studies in group 3. Numerical values are the *p* values for the two-tailed paired *t* test at each point.

possible to obtain any hemodynamic data from this animal. There were no cardiomyostimulator- or lead-related problems in this series, and only one minor wound infection that settled with conservative management.

Data were therefore available for analysis from 5 of the 6 animals in group 1, 4 of the 5 animals in group 2, and 5 of the 6 animals in group 3.

The preinfarction, 1 hour postinfarction, and baseline 3-month postoperation measurements were first compared for the following indices: heart rate, systolic aortic pressure, diastolic aortic pressure, mean aortic pressure, systolic LV pressure, end-diastolic LV pressure, systolic pulmonary artery pressure, diastolic pulmonary artery pressure, mean pulmonary artery pressure, mean pulmonary artery capillary wedge pressure, right atrial pressure, cardiac output, positive time derivative of LV pressure (dp/dt), negative LV dp/dt , stroke volume, stroke work, cardiac power, systemic vascular resistance, and pulmonary vascular resistance.

Left ventricular end-diastolic pressure was measured from the LV pressure curve, and was taken to occur at the beginning of the rapid upstroke of the dp/dt [8].

Having done this, the function curves created by plotting an index on the *y* axis against the volume transfused on the *x* axis were then compared for the same set of indices. Representative function curves are shown in Figures 1 to 5; for economy of space all the curves are not shown. The *p* values for the various significance tests are shown in Tables 1 to 7.

Preinfarction and Postinfarction Data

In the comparison between groups 1 and 3, their weights were similar as were their initial hemodynamic measure-

Fig 2. Graph of end-diastolic left ventricular pressure against volume of colloid transfused during the terminal studies in group 3. Numerical values are the *p* values for the two-tailed paired *t* test at each point.

ments. There are two exceptions to this, the differences in pulmonary artery capillary wedge pressures (9.6 ± 0.83 mm Hg for group 1 and 5.8 ± 1.04 mm Hg for group 2; $p = 0.032$) and the differences in right atrial pressures (5.0 ± 0.49 mm Hg for group 1 and 1.6 ± 0.92 mm Hg for group 2; $p = 0.005$). There was just one statistically significant difference in the 1-hour postinfarction data, with the pulmonary artery diastolic pressure being 15.0 ± 2.61 mm Hg for group 1 and 13.2 ± 1.71 mm Hg for group 2 ($p = 0.049$).

Likewise, in the comparison between groups 1 and 3, their weights were similar as were their initial hemodynamic measurements. In the immediate postinfarction period there was no difference between groups 1 and 3. This is important as it implies that an equality of infarct area was achieved and therefore that the aneurysms, and hemodynamic impairment, produced were similar in the two groups.

Comparing the control data for the groups 2 and 3, there were small differences before infarction in the pulmonary artery capillary wedge pressure and the right atrial pressure. For group 2, pulmonary artery capillary wedge pressure was 5.8 ± 1.04 mm Hg, and for group 3, it was 6.8 ± 1.86 mm Hg ($p = 0.027$). For group 2, right atrial pressure was 1.6 ± 0.92 mm Hg, and for group 3, it was 3.4 ± 1.43 mm Hg ($p = 0.002$). These differences were abolished after coronary artery ligation, and by 1 hour after coronary artery ligation there were no significant differences between these two groups. These results confirm that these groups were all comparable with each other at the outset of their recovery phase and muscle transformation protocol.

Baseline Terminal Studies

A major criticism of clinical cardiomyoplasty has been the discordance between the patients' reported improvement

Fig 4. Graph of peak positive left ventricular dp/dt against volume of colloid transfused during the terminal studies in group 3. Numerical values are the *p* values for the two-tailed paired *t* test at each point.

in symptomatology and their apparent lack of improvement in noninvasive indices of LV function at rest. Indeed, this is confirmed in this experimental model, where if we consider the baseline differences at the terminal studies, it can be seen that the only differences between groups 1 and 3 (see Table 2) lies in a slower heart rate in group 3, both with the cardiomyostimulator turned off (102.2 ± 3.43 versus 88.4 ± 5.17 beats/min; $p = 0.024$) and when it is turned on (102.2 ± 3.43 versus 79.6 ± 4.42 beats/min; $p = 0.006$).

There are similarly no differences between groups 1 and 2 (see Table 1) or between groups 2 and 3 at the baseline terminal studies (see Table 3), although there is a ten-

failure that exercise testing and assessment of exercise hemodynamics and metabolism is highly significant. Obviously in the anesthetized and instrumented sheep this is difficult, and therefore we elected to study these animals by worsening their heart failure by volume loading. This is justified as normal humans do not show an increase in preload indices during exercise, whereas patients with heart failure will show significant increases in pulmonary artery capillary wedge pressures [9].

Volume loading to a total of 2,500 mL of colloid plasma expander is a severe challenge, particularly to an animal of only 40 kg, even without an already impaired heart. There was noticeable tissue edema by the end of the procedure, and endotracheal suction often produced frothy fluid after approximately 2,000 mL of plasma expander had been transfused. Hemodilution was apparent, with marked decreases in hemoglobin levels by the end of the procedure.

To create true Frank-Starling curves it would be necessary to plot LV end-diastolic volume against the systolic indices at a constant heart rate. To obtain a constant heart rate would have required inserting a temporary endovenous pacing wire, without x-ray screening. Although this is feasible, particularly with a pacing Swan-Ganz catheter, it would still have been necessary to insert a second pulmonary artery catheter. Furthermore, the higher heart rate required presented the risk of inducing Wenckebach of the cardiomyostimulator, which would have added a further variable to the study. For these reasons we elected to leave heart rate uncontrolled.

Comparison of Groups 1 and 2

If we consider first the comparison of the function curves from group 1 with those from group 2 (see Table 4), then we see that only the curves for diastolic pulmonary artery pressure, with a p value by ANOVA of 0.034, are significantly different. Furthermore, there is little sign that any of the other curves would be likely to be significantly different if the numbers of animals in each group were increased. It is apparent from this that simply applying an unstimulated muscle wrap to an infarcting area of the left ventricle, in this model, does not improve the function of the remaining myocardium.

Comparison of Cardiomyostimulator Off Against On in Group 3

If the function curves for the various indices against volume loading are compared within group 3 (see Table 7), the dynamic cardiomyoplasty group, then it can be seen that comparing the cardiomyostimulator on with the cardiomyostimulator off shows changes in the indices of preload (LV end-diastolic pressure, pulmonary artery capillary wedge pressure, mean pulmonary artery pressure, right atrial pressure) and the derived indices of function (stroke volume, stroke work) while there is little or no change in the direct indices of systolic function (systolic aortic pressure, systolic LV pressure). Left ventricular dp/dt shows a significant change, whereas heart rate does not.

If some of these curves are considered in more detail, there is a definite increase in cardiac output after the

cardiomyostimulator is activated. This is clearly seen from the curve in Figure 1, and is of greatly increased significance with the decrease in indices of preload (see Figs 2, 3). The p value by ANOVA is 0.005. As would be expected, there is a progressive increase in cardiac output as the animals were volume loaded. Figure 1 shows the curves, with the significance values by paired two-tailed t tests entered onto the curves. It is apparent from this figure that there is an increasing effect from the cardiomyoplasty as the animals are volume loaded, with a p value of 0.018 at +1,500 mL and 0.004 at +2,000 mL.

The changes in indices of preload have been mentioned above. The directly measured LV end-diastolic pressure shows the expected increase from its already elevated level with serial volume loading (see Fig 2). At each point the institution of muscle stimulation produces a decrease in the pressure, although this decrease is most marked in the middle of the volume loading range. Figure 2 shows the p values by a paired two-tailed t test entered onto the curves of LV end-diastolic pressure. Similarly to the cardiac output curve, significant differences can be seen at the +1,500 mL and +2,000 mL points, with p values of 0.007 and 0.016, respectively. There is also a significant improvement at the +1,000 mL point, with a p value of 0.009.

The mean pulmonary artery capillary wedge pressure shows a similar decrease when muscle flap stimulation is instituted on top of the expected increases with volume loading. Figure 3 shows the p values by a paired two-tailed t test entered onto the curve. As would be expected, this curve is very similar to the LV end-diastolic pressure curve, in spite of being measured with a different type of transducer. The p values at +1,000 mL, +1,500 mL, and +2,000 mL are all significant, with values of 0.003, 0.007, and less than 0.001, respectively.

The curves for systolic, diastolic, and mean pulmonary artery pressure all suggest that there is a decrease in pulmonary artery pressures with cardiomyoplasty, with the curves for systolic and mean pulmonary artery pressures reaching significance at p values by ANOVA of 0.026 and 0.042, respectively.

The decrease in systemic vascular resistance is most likely to be a homeostatic mechanism to normalize arterial pressures at a constant level with the increased cardiac output, and as such is the probable explanation for the failure of the arterial pressures to increase with cardiomyoplasty.

The maximum LV dp/dt shows a consistent increase when the cardiomyostimulator was switched on, and the maximum LV dp/dt also shows a serial increase with volume loading. Figure 4 shows the significance values of two-tailed paired t tests on the curves for maximum LV dp/dt. It is interesting to note that whereas the differences from +500 mL to +2,500 mL are all significant, it is the differences at +1,000 mL and +1,500 mL that are the most prominent. This is in good agreement with the rest of the hemodynamic data.

Although the sensitivity of dp/dt to changes in preload and afterload is disputed, it is an isovolumic contractile index that is sensitive to changes in "inotropic state" [10, 11]. It is difficult from our data to determine whether the

increase in dp/dt is the primary event, or whether the increase in dp/dt is reflecting a decrease in systemic vascular resistance, which is in its own turn due to the increased cardiac output. It is clear though that there is an increase in left ventricular performance whether it is measured by the LV dp/dt , the cardiac output, or both. Recent experimental evidence in humans [12] suggests that dp/dt is independent of both preload and afterload, and therefore these animals are showing a primary improvement in LV contractility with dynamic cardiomyoplasty.

It would be reasonable to suggest that the improved ventricular function created by turning the cardiomyostimulator on leads to an improved cardiac output, a decrease in the indices of preload, and a maintenance of the arterial blood pressure by a reflex decrease in systemic vascular resistance. A beneficial side effect of this is a decrease in the subendocardial perfusion gradient (diastolic aortic pressure minus LV end-diastolic pressure) with a consequent increase in oxygen delivery to this important region.

There are a series of important indices that can be derived from these data. Stroke volume is the simplest, and this shows a significant and consistent increase with cardiomyoplasty. This reaches significance by ANOVA at a p value of 0.004. Interestingly, the highest percentage increases in stroke volume are seen in the mid and upper range of the curves. The increase with the cardiomyostimulator turned on is only 4.6% at the baseline, 10.4% at +500 mL, 15.1% at +1,000 mL, 10.6% at +1,500 mL, and 14.9% at +2,000 mL. Figure 5 shows the values for significance from the two-tailed paired t tests, and the percentage improvements noted above were all significant when the underlying data were examined.

The stroke work has been calculated using the aortic pressure data. The curves show significant increases in stroke work, with a p value by ANOVA of 0.006. This finding is to be expected from the decreases in the preload indices and the increases in cardiac output and hence stroke volume.

Cardiac power has been calculated according to the formula of Tan and associates [13]. This is a formula that has been put forward to improve the assessment of cardiac function in heart failure. The increase in cardiac power when the cardiomyostimulator is switched on is further evidence that the cardiomyoplasty is contributing to cardiac performance.

Whereas the calculated increases in stroke volume, stroke work, and cardiac power are derived measurements from the cardiac output, the increase in LV dp/dt is a directly measured index of improved ventricular contractility. It could be argued that it is unsafe to place too much reliance on a single measurement, or a series of measurements that are essentially derived from the same original measurement. It could also be argued that stroke volume, stroke work, and cardiac power are very closely related, and therefore do not lead to any increased support for the hypothesis over and above the improvement seen in cardiac output. However, the measurement of cardiac output and LV dp/dt are not significantly related. Furthermore, for all the discussion of the merits of LV

dp/dt as an index of contractility, there is no suggestion that it should increase with a decrease in LV end-diastolic pressure. Therefore the decrease in LV end-diastolic pressure seen here at the same time as an improvement in cardiac output and stroke volume is an additional and independent support for the assumption that the cardiomyoplasty is contributing to the increase in cardiac power. The similarities in behavior of pulmonary artery capillary wedge pressure and LV end-diastolic pressure are of mutual support as the two measurements are made with different systems. Therefore, each measurement supports the validity of the other.

There are now two further issues of importance, these being the differences in performance between group 3 and groups 1 and 2. Both groups 1 and 2 need to be compared with both the cardiomyostimulator off and cardiomyostimulator on data from group 3.

Comparison of Groups 1 and 3

Comparing group 1 and the cardiomyostimulator off data by ANOVA, it can be seen that the only significant difference is a lower heart rate in group 3 ($p = 0.007$ by ANOVA). When group 1 is compared with the cardiomyostimulator on data from group 3, this difference is maintained (see Table 5), and there are now significant decreases in systolic pulmonary artery pressure and pulmonary artery capillary wedge pressure. These differences have p values by ANOVA of 0.011 and 0.023, respectively. Inspection of Table 2 shows that the changes are not significant between the groups at baseline by unpaired two-tailed t tests. However, these changes become significant as the animals are volume loaded and the two curves diverge.

There are trends toward lowered LV end-diastolic pressure ($p = 0.057$ by ANOVA) and, to a lesser degree, mean pulmonary artery pressure ($p = 0.087$ by ANOVA). The curve for LV end-diastolic pressure shows a similar pattern to those of systolic pulmonary artery pressure and pulmonary artery capillary wedge pressure; however, the individual points all fail to reach significance.

Stroke volume shows a trend toward increasing, with a p value of 0.068. The p values for unpaired two-tailed t tests show a trend toward a difference between the two groups in the earlier part of the function curve. Although there are definite indicators of improved function with cardiomyoplasty when compared against the control group, the changes are not as clear as they were in the straightforward off-on studies within group 3.

Comparison of Groups 2 and 3

It is interesting that in the comparison between group 2 and group 3, although with the cardiomyostimulator off there is no difference between the two groups, differences become apparent in the comparison between group 2 and the cardiomyostimulator on data of group 3 (see Table 6). The distribution of improvement is similar to that seen in the off-on studies of group 3 itself. All the pulmonary artery pressures are lowered with the cardiomyostimulator on, the p values being 0.023 for systolic, 0.018 for diastolic, and 0.015 for mean pulmonary artery pressure. The decrease in pulmonary artery capillary wedge pres-

sure is significant at $p = 0.008$, and that of right atrial pressure at $p = 0.010$. Cardiac output tends to increase ($p = 0.067$), whereas stroke volume just reaches significance ($p = 0.047$). Stroke work is further away from significance ($p = 0.093$).

Mechanism of Improved Ventricular Performance

The improved ventricular performance cannot be solely due to a "splinting" of the heart by the latissimus dorsi muscle; if this were so then there would not be any improvement in cardiac output when the cardiomyostimulator was switched on in group 3, nor would there be a difference between groups 2 and 3.

It has also been shown from acute experiments [14] that the orientation of the wrap used in this study is an inefficient method for transferring energy from muscle contraction to mass transport of blood. Even with the most carefully constructed cardiomyoplasty, in the orientation used in this study, it is not unusual for coverage of the infarcted region with paced skeletal muscle to be incomplete. The usual explanation for the clinical improvement seen after cardiomyoplasty is that the heart is "squeezed" by the muscle wrap as it contracts. Indeed this may be so, which implies therefore that the improvements seen in cardiac performance in this model underestimate those that could be seen if the wrap were to be completed by patch extension of the muscle.

There is an alternative suggestion that at least part of the transfer of energy from the muscle to the blood stream comes about as a result of forceful displacement of the heart within the mediastinum. It is harder to visualize the exact mechanism by which this might occur, although in the model used here it was obvious that there was substantial potential for cardiac displacement to occur.

Recently, though, there has been increasing discussion that the changes in wall stress produced by the muscle wrap, in particular the decrease produced by the thickening of the ventricle, are of importance [1]. It is clear that the wall stress at the aneurysm is greatly decreased by the thickening of the wall from the 1 or 2 mm of the fibrous aneurysm to the 5 to 15 mm of the muscle-wrapped aneurysm. Presumably this will normalize the stress pattern within the contracting left ventricle, allowing mechanically more efficient contraction at a lower energy, and oxygen, consumption. Indeed, it has recently been pointed out that not only is there a very marked increase in regional wall stress index in the aneurysm itself, but the increase only declines slowly in the transition zone between the aneurysm and the remote normal myocardium [15]. However, the similarity in function curves between the adynamic myoplasty and the control group shows that simply decreasing the regional wall stress index by thickening the aneurysm with the muscle wrap does not on its own improve cardiac function.

Ventricular Relaxation

The curve for the peak negative LV dp/dt , the fastest rate at which intraventricular pressure is declining, is the best index in this study of ventricular relaxation [11, 16, 17]. There is no correlation between the use of the cardiomyostimulator and changes in the negative LV dp/dt ; indeed,

there is little change between the values at the beginning and the end of the volume loading experiment. There has been considerable concern that cardiomyoplasty could slow ventricular relaxation and therefore would inhibit ventricular filling. Certainly in this model there is no evidence for this hypothesis, although there is an important difference in this model of cardiomyoplasty: in these experiments, the wrap was incomplete, being passed over the free wall of the left ventricle and the anterior wall of the right ventricle, and around the apex. Although this allowed a model in which the animals could survive the procedure, it did not allow for direct comparison of the effects of ventricular relaxation with other models of cardiomyoplasty.

Improving the Model

This model of cardiomyoplasty probably underestimates the effect of skeletal muscle support, as the wrap is incomplete and the tendon of the latissimus dorsi was left intact, rather than being divided and sutured to a rib. It was very obvious that when the animals were anesthetized and on their sides there was a very considerable amount of shoulder movement. When the shoulder was stabilized, the arterial pressures could be seen to increase. Although all the measurements were made with the shoulder stabilized, there still remained some forelimb movement. This movement creates a variable degree of mechanical instability, with consequent inefficiency of power transfer between the working muscle and the heart. It is highly likely that the changes with institution of muscle pacing could be further improved by attention to these two points.

Conclusion

It is possible to produce a model of experimental dynamic cardiomyoplasty in chronic LV failure. Although the model we have used has mechanical limitations to energy transfer between the latissimus dorsi muscle flap and the blood stream, it has still shown highly significant improvements in indices of cardiac function. This has been seen both within the dynamic cardiomyoplasty group, when the stimulator on is compared with the stimulator off situation, and also when the stimulator on is compared with the control group and the adynamic cardiomyoplasty group. The enhancements seen under stress lend support to both the symptomatic upgrade and the improvements in indices of function, during exercise, seen in patients [18].

Mr Millner is the recipient of a British Heart Foundation Junior Fellowship. We would like to thank the Medtronic Company, Bakken Research Center, Maastricht, Holland, for the supply of cardiomyostimulators and pacing leads, and the St. George's Hospital Medical Research Committee for financial support.

Late Results After Triple-Valve Replacement With Various Substitute Valves

Paul S. Brown, Jr, MD, Charles S. Roberts, MD, Charles L. McIntosh, MD, PhD, Julie A. Swain, MD, and Richard E. Clark, MD

Surgery Branch, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland

The purpose of this study was to determine what influence various combinations of mechanical and bioprosthetic valves in the aortic, mitral, and tricuspid positions had on late morbidity and mortality of 40 hospital survivors of triple-valve replacement. At operation the patients ranged in age from 27 to 69 years; 73% were women. The mean postoperative follow-up interval was 8.3 years, with a total follow-up of 331 years (100% complete). At 12 months after operation, functional class decreased from 3.3 to 1.6 ($p < 0.05$), cardiac index increased from 2.0 to 2.6 L · min⁻¹ · m⁻² ($p < 0.05$), and pulmonary artery pressures decreased from 59/27 to 40/17 mm Hg ($p < 0.05$). There were no differences in preoperative variables between groups. Actuarial survival for the 40 patients (exclusive of 30-day or in-hospital mortality, which was 31%) was 78% and 74% at 5 and 10 years. At the same milestones, freedom from reoperation was 96% and 54%, freedom from combined thromboembolism and anticoagulant-related hemorrhage was 68% and 56%, and freedom from all late valve-related morbidity

and mortality was 64% and 25%. Comparison of the patients with two or more mechanical prostheses with the patients having two or more bioprostheses indicated no significant differences in actuarial freedom from late death, thromboembolic events, or anticoagulant-related hemorrhage. However the actuarial freedom from reoperation in the groups with two or more mechanical valves was lower than that of the groups with two or more bioprosthetic valves (0/10 versus 13/30; $p < 0.05$). Among 13 patients having reoperation, reoperation in 12 was prompted by degeneration of one or more bioprosthetic valves. Six of the patients who underwent reoperation died in the hospital, and 4 others died between 2 and 8 years after operation. These results support the view that mechanical prostheses provide better long-term results for triple-valve replacement than those produced using bioprostheses, primarily by reducing need for reoperation and its attendant complications.

(*Ann Thorac Surg* 1993;55:502-8)

Results of triple cardiac valve replacement have been reported by many groups of investigators [1-9]. Few reports, however, have compared late results of simultaneous aortic, mitral, and tricuspid valve replacement at the same institution using different types of substitute valves [8, 9]. The purpose of this study was to determine if various combinations of mechanical and bioprosthetic valves influenced late morbidity and mortality in patients undergoing triple-valve replacement. This report describes such results in 40 hospital survivors of triple cardiac valve replacement at the National Heart, Lung and Blood Institute (NHLBI) over a 25-year period.

Material and Methods

A total of 63 patients underwent simultaneous aortic, mitral, and tricuspid valve replacement at the NHLBI from 1966 to 1990. Twenty-three patients were excluded from this analysis of late results. Twenty died within 30

days of operation or during initial hospitalization, and 3 patients who were referred from Iran, Romania, and Greece returned to their countries of origin immediately after operation and could not be followed up.

The remaining 40 patients were separated into four groups based on the types of substitute valves inserted. Five patients received mechanical prostheses in the aortic, mitral, and tricuspid positions, 5 received mechanical prostheses in the aortic and mitral positions and a bioprosthesis in the tricuspid position, 17 received a mechanical prosthesis in the aortic position and bioprostheses in the mitral and tricuspid positions, and 13 received 3 bioprostheses (Table 1). Although different valve combinations were placed over different time periods, it is expected that advances in myocardial protection and surgical technique would have a greater influence on short-term as opposed to long-term survival.

The 23 excluded patients had the following valves implanted: mechanical prostheses in 3, two mechanical prostheses and one bioprosthesis in 3, one mechanical prosthesis and two bioprostheses in 7, and three bioprostheses in 10. There were no significant differences between the patients who were excluded and the remaining 40 patients in terms of the types of valves or combinations of valves inserted.

AV = aortic valve; AVR = aortic valve replacement; BP = bioprosthesis; BS = Björk-Shiley; H = Hancock; KS = Kay-Shiley; MC = mitral commissurotomy; MP = mechanical prosthesis; MV = mitral valve; MVR = mitral valve replacement; SE = Starr-Edwards; SJM = St. Jude Medical; TV = tricuspid valve; TVR = tricuspid valve replacement.

The end of the study was January 1, 1990, and all patients who were still alive were contacted within 2 months of this date. Follow-up was achieved primarily by yearly outpatient clinic visits, the records of which were reviewed. The duration of follow-up per patient ranged from 0.2 to 19.5 years (mean, 8.3 years), with a total of 331 years for 40 patients (100% complete). The ages of the 40 patients ranged from 27 to 69 years at operation (mean, 49 years); 73% were women. Eighteen of the patients had undergone a previous cardiac valve operation and 90% were in atrial fibrillation. A history of acute rheumatic fever was reported by 28 patients. No patient had active infective endocarditis at operation.

The population of patients of the Surgery Branch of the NHLBI was unique in that there was accurate ongoing follow-up of all patients in the outpatient clinic every 1 to 2 years for life. All underwent complete preoperative evaluation, and 38 of the 40 patients had a postoperative cardiac catheterization at less than 9 months during a rehospitalization for extensive studies. A physical examination, electrocardiogram, chest radiograph, and echocardiogram were obtained at each clinic visit. Any patient with a change in symptom complex or new echocardiographic findings underwent cardiac catheterization. If a clinic appointment was missed, the patient and the private physician were contacted to find out the status of the patient. Outside cardiac catheterization results were entered into the database, as were the cause of death or autopsy results.

Morbidity and mortality results for each group were expressed in both linearized (percent/patient year) and actuarial terms. Preoperative and postoperative data between groups were compared using unpaired Student's *t* tests, and data within the same group were compared using paired Student's *t* tests. Kaplan-Meier actuarial data were compared by the Mantel-Haenszel test. Total mortality as expressed in Table 3 included all deaths during

the follow-up period. However, in the actuarial survival analysis, the patients who underwent reoperation or who died of noncardiac causes were withdrawn from further analysis on that particular date and were not treated as having died. The actuarial analysis of complications (thromboembolism, anticoagulant-related hemorrhage, and reoperation) included only first events, fatal or non-fatal. Thromboembolism was defined as any new postoperative neurological or systemic ischemic deficit, whether central or peripheral, temporary or permanent. Patients on anticoagulant or antiplatelet agents with episodes of hemorrhage causing death, stroke, hospitalization, transfusion, or operation were classified as having anticoagulant-related hemorrhage [10]. Those patients taking warfarin, but with subtherapeutic prothrombin times at the time of a morbid event, were classified as having a thromboembolism rather than anticoagulant-related hemorrhage. In the patients receiving warfarin, a prothrombin time of 1.5 to 2 times normal was recommended.

Valve-related morbidity and mortality included all late deaths, reoperations, thromboembolism, and anticoagulant-related hemorrhage but excluded patients who died in end-stage congestive heart failure with normally functioning prosthetic valves or documented noncardiac deaths. Note that this is a measure of valve-related late morbidity and mortality and specifically excludes 30-day and in-hospital mortality, which was 31%.

Two of the 23 excluded patients had a thromboembolic event at less than 30 days (both with two mechanical prostheses and one bioprosthesis combination); both events were strokes, and the patients eventually died of pneumonia and coma. The other deaths in this group were caused by low cardiac output syndrome (6), coagulopathy (3), myocardial infarction (2), multisystem organ failure (2), sepsis (1), pneumonia (1), diverticulitis (1), perforated ulcer (1), and arrhythmia (1).

Results

No significant differences among the four groups of patients were found in age at operation, frequency of history of rheumatic or infective endocarditis, atrial fibrillation, mean functional class, pulmonary arterial pressure, or cardiac index. All 40 patients underwent cardiac catheterization before operation (<9 months). The mean postoperative functional class improved significantly from 3.3 to 1.6 ($p < 0.05$). Thirty-five of the 40 patients underwent cardiac catheterization postoperatively. The mean pulmonary arterial systolic/diastolic pressures decreased from 59/27 to 40/17 mm Hg ($p < 0.05$), and the mean cardiac index increased from 2.0 to $2.6 L \cdot \min^{-1} \cdot m^{-2}$ ($p < 0.05$) (Tables 2, 3). Twenty-nine of the 40 patients took warfarin, including all 27 patients who had a mechanical prosthesis and 2 of the 13 patients who had three bioprostheses because of atrial fibrillation.

Survival

The actuarial survival of the 40 hospital survivors was 78%, 74%, and 44% at 5, 10, and 15 years (Fig 1). The differences among the four groups were not significant at any of these three intervals (Fig 2). The mortality expressed in linear terms ranged from 4.0 to 7.7%/year.

Twenty-one patients died during the follow-up period: 6 patients of chronic congestive heart failure, 1 of intracerebral hemorrhage while taking warfarin, 1 of cancer, and 3 of natural causes. Ten patients died after reoperation to replace one or more of the substitute valves, of whom 6 died before hospital discharge and 4 died late after reoperation (2 to 8 years).

Reoperation

Actuarial freedom from reoperation at 5 and 10 years was 96% and 54% (see Fig 1). The rate of reoperation in groups with three bioprostheses or with one mechanical prosthesis and two bioprostheses was significantly higher ($p < 0.05$) than that in the groups with three mechanical prostheses or two mechanical prostheses and one bioprosthesis at 10 and 15 years (Fig 3). Rereplacement was required in 13 (33%) of the 40 patients, a frequency of 3.9%/year (Table 4). The mean interval from triple-valve replacement to reoperation was 8.4 years. No patient in the group with three mechanical prostheses or the group with two mechanical prostheses and one bioprosthesis required reoperation. Nine (53%) of the 17 patients in the group with one mechanical prosthesis and two bioprostheses underwent reoperation. The mitral bioprosthesis

Fig 1. Actuarial curves of freedom from reoperation, death, and all valve-related late morbidity and mortality (M + M) in 40 hospital survivors of combined aortic, mitral, and tricuspid valve replacement. Patients who required reoperation were censored at the time of reoperation on the survival analysis.

was replaced in 8 of these patients, all of whom had bioprosthetic structural deterioration, and in 1 patient who had isolated replacement of a mechanical aortic prosthesis because of recurrent thromboembolic events (see Table 4, patient 1). Four of the 13 patients in the group with three bioprostheses underwent reoperation, with the mitral bioprosthesis being replaced in each patient. All 13 patients who underwent reoperation had a bioprosthesis in the tricuspid and mitral positions; replacement of the bioprosthesis in the tricuspid position was carried out in 9 patients, although prosthetic tricuspid valve disease was not the primary reason for reoperation. The in-hospital mortality for reoperation after triple cardiac valve replacement was 46% (6/13 patients), with an additional 4 patients dying 2 to 8 years after reoperation.

Fig 2. Comparison of actuarial curves of freedom from death in 40 hospital survivors of combined aortic, mitral, and tricuspid valve replacement with four different combinations of substitute valves. Patients who required reoperation were censored at the time of reoperation. (AV = aortic valve; BP = bioprosthesis; MP = mechanical prosthesis; MV = mitral valve; TV = tricuspid valve.)

Fig 3. (AV = aortic valve; BP = bioprosthesis; MP = mechanical prosthesis; MV = mitral valve; TV = tricuspid valve.)

Thromboembolism and Anticoagulant-Related Hemorrhage

Freedom from combined thromboembolism and anticoagulant-related hemorrhage, expressed in actuarial terms, was 68% and 56% at 5 and 10 years for all 40 patients (Figs 4, 5). Thromboembolism occurred in 11 of the 40 patients (3.3%/year). Seventy-five of the patients who presented for postoperative cardiac catheterization were in atrial fibrillation. Eight of 11 patients with thromboembolism were in and out of atrial fibrillation at the time of their event. These events occurred only in patients who had a mechanical prosthesis, and only one of these events was fatal (Fig 6). Anticoagulant-related hemorrhage occurred in 6 of the 40 patients. No patient in the group with three bioprostheses had this complication, and no event was fatal (Fig 7). Four of 6 patients were in atrial fibrillation at the time of hemorrhage. Patients with one or more mechanical prostheses had significantly higher rates of these complications than did those patients without a mechanical prosthesis ($p < 0.05$) (see Fig 5). The one mechanical prosthesis/two bioprostheses combination had the highest occurrence of thromboembolism, and 14 of 17 patients in this group had a Björk-Shiley mechanical aortic prosthesis.

Freedom from all valve-related morbidity and mortality was 65%, 25%, and 20% at 5, 10, and 15 years (see Fig 1). The group of patients with two or more mechanical prostheses had a lower freedom from all late valve-related morbidity and mortality at 10 years than did the group with two or more bioprostheses (Fig 8). Also not reflected in Figure 8 is the fact that reoperation in the groups with two or more bioprostheses was associated with considerable mortality.

Comment

Analysis of results of triple-valve replacement is more complex than that of single- or double-valve replacement. The same patient may have different types of substitute

valves inserted, and different patients may have many combinations of the same valves. Because triple-valve replacement is an infrequently performed operation, acquisition of sufficient data for meaningful analysis requires long intervals during which procedures, surgeons, valve preferences, and availability of valve types change. The patient population in the present study was seen during a 25-year period, with 6 different surgeons performing triple-valve replacement in the 63 described patients.

In the present study, the number of patients having a mechanical prosthesis in all three valve positions was too small to make meaningful comparison with the group with a bioprosthesis in all positions. However comparison of the 10 patients with two or more mechanical prostheses

with the 30 patients with two or more bioprostheses indicated no significant differences in frequency of thromboembolic events (2/10 versus 9/30), anticoagulant-related bleeding (1/10 versus 5/30), or late death (4/10 versus 17/30). The late death rate changes to 1 of 10 and 3 of 30 when the deaths due to end-stage congestive heart failure and after reoperation are censored. Reoperation in 12 of the 13 patients was prompted by degeneration of one or more bioprostheses. Twelve of the 30 bioprostheses in the mitral position and nine of the 35 bioprostheses in the tricuspid valve position were replaced. No patient with a mechanical prosthesis in both left-sided valve positions had reoperation.

Fig 6. Comparison of actuarial curves of freedom from thromboembolism (TE) in 40 hospital survivors of combined aortic, mitral, and tricuspid valve replacement with four different combinations of substitute valves. (AV = aortic valve; BP = bioprosthesis; MP = mechanical prosthesis; MV = mitral valve; TV = tricuspid valve).

Neither the early nor late results of triple-valve replacement described above are ideal. Of 63 patients initially having triple-valve replacement, 31% died in the early postoperative period, and of the remaining 40 patients, 52% died later. Nevertheless, the New York Heart Association functional class improved by 1 class or more in 90% of patients, with 45% becoming class I (asymptomatic). Patients with a bioprosthesis in one or both left-sided valve positions had a significantly higher reoperation rate compared with those in whom both left-sided cardiac valves were replaced with a mechanical prosthesis. Thus, these data provide evidence that use of bioprostheses for triple-valve replacement is not ideal.

Other factors also provide evidence that bioprostheses should be avoided, at least for replacement of the mitral and aortic valves and probably also for the tricuspid valve. In the present study, 45% of the 40 patients had one (12

(AV = aortic valve; BP = bioprosthesis; MP = mechanical prosthesis; MV = mitral valve; TV = tricuspid valve.)

patients) or two (6 patients) cardiac operations before the triple-valve replacement. All of these 18 patients were among the 35 in whom one or more bioprostheses were inserted at triple-valve replacement. It is well established from numerous studies in the last 20 years that a porcine bioprosthesis in any valve position will degenerate if the patient survives a sufficiently long time [9, 11-13]. Five patients who later had reoperation after triple-valve replacement had already undergone one or more valve operations before triple-valve replacement. Thus, reoperation in 3 patients represented their fourth cardiac valve operation, and 2 of them died early postoperatively.

Reported experience with use of a mechanical prosthesis for tricuspid valve replacement has not been encouraging [14-17]. Most reports, however, have provided results using a mechanical prosthesis that today is either never used or rarely used for tricuspid valve replacement. Only 5 of our 40 patients had the tricuspid valve replaced with a mechanical prosthesis: Starr-Edwards in 1, Kay-Shiley in 3, and Björk-Shiley in 1. These three types of mechanical prostheses are rarely used today for tricuspid valve replacement. In contrast, early results of replacement of the tricuspid valve with a St. Jude Medical valve are encouraging [18, 19].

Any study reporting results of tricuspid valve replacement can legitimately ask whether its replacement was necessary in the first place [20-24]. It is relatively easy to justify tricuspid valve replacement in a patient with severe rheumatic tricuspid stenosis, as was the situation in 18 (45%) of our 40 patients. Disagreement on the need for tricuspid valve replacement centers on the purely regurgitant tricuspid valve (no element of stenosis), which was present in 22 (55%) of our patients. When the right ventricular systolic pressure is less than 40 mm Hg, the purely regurgitant tricuspid valve is usually anatomically abnormal. Such hemodynamics were present in 2 of our 40 patients. Thus, 20 of our 40 patients had pure tricuspid

regurgitation with elevated right ventricular systolic pressure. Most, if not all, of these patients would probably undergo tricuspid valve annuloplasty today rather than tricuspid valve replacement [21-23].

Data from this analysis support the view that patients having triple-valve replacement have fewer total complications and greater longevity when both left-sided valves are replaced with a mechanical prosthesis. The evidence is not yet available to show that a low-profile, ventral flow mechanical prosthesis, such as the St. Jude Medical, provides better outcome than does a bioprosthesis when used in the tricuspid position. It would seem most advantageous, however, if all three valves could be mechanical ones, the advantage being that valve degeneration (and therefore reoperation) would be far less likely. Combining mechanical and bioprosthetic valves in the same patient, especially if the patient already has to be anticoagulated, imparts the disadvantages of both valve types and the advantages of neither.

Bilateral Intralobar Pulmonary Sequestration With Horseshoe Lung

Marcial M. Cerruti, MD, Fausto Marmolejos, MD, and Thomas Cacciarelli, MD

Department of Thoracic Surgery, Maimonides Medical Center, Brooklyn, New York

We present an unusual case of a young woman with a several-month history of bronchopulmonary infection, symptomatic on the left side, who underwent complete studies showing bilateral pulmonary sequestration with suspected bridging tunnel. A bilateral resection was performed as a single procedure through a left thoracotomy.

(*Ann Thorac Surg* 1993;55:509-10)

Itralobar pulmonary sequestration is a segment of pulmonary parenchyma not connected to the tracheo-bronchial tree, within the normal pleural investment, receiving arterial supply from the systemic circulation and venous return usually through pulmonary veins and rarely through systemic venous drainage [1]. This lesion, whether congenital or acquired [1], occurs mainly in the basal segments of the lower lobes and is more frequently unilateral than bilateral. In 400 reported cases of intralobar sequestration, Savic and associates [2] found only 2 cases of bilateral intralobar sequestration.

The horseshoe lung [3, 4] is a very rare congenital malformation in which the basal segments of both lower lobes are fused by an isthmus of pulmonary tissue behind the heart. It may be associated with the scimitar syndrome, in which the leading feature is an anomalous drainage of some or all of the pulmonary veins of the right lung which, in turn, may be associated with other congenital malformations.

A 20-year-old woman with a 7-month history of recurrent bronchopulmonary infection was not responding to medical treatment and continued to have productive cough, fever, and weight loss. She was symptomatic on the left side only. A chest roentgenogram showed pulmonary density and infiltrate involving the basal segments of the left lower lobe. Computed tomographic scan of the chest showed bilateral pulmonary lesions on the left and right lower lobes (consistent with bilateral intralobar sequestration), more prominent on the left side, with a possible bridging tunnel but no clear evidence of abnormal vessels (Fig 1). The angiogram revealed arterial supply from the abdominal aorta to the left sequestered segment and from the thoracic aorta, which bifurcated, to the right and left lower lobe sequestrations. Venous drainage was into the

inferior pulmonary vein on the left side, but not clearly demonstrated on the right side (Fig 2).

The plan was to resect the symptomatic sequestration on the left side and then to consider resection of the lesion on the right side.

A left thoracotomy was performed. A lobectomy was decided on because an irregular mass was found occupying the basal segments of the lower lobe, with severe collateral inflammatory infiltration around it and extending into the superior segment. Three small arteries coming through the diaphragm were divided. The inferior pulmonary ligament and adjacent portion of the lower lobe were fixed to the mediastinum by what, on dissection, proved to be the connecting tunnel with a central orifice. Purulent secretion was draining from the right and left sides of this orifice. The tunnel measured 3 cm in diameter and extended behind the heart, entering the right pleural cavity and reaching the basal segments of the right lower lobe, where a well-demarcated area of about 3 × 6 cm was the right lower lobe sequestration. This portion of the right lower lobe and the connecting tunnel were brought into the left pleural cavity, and a wedge resection of the sequestered area was done (Fig 3). It is important to mention that during the dissection of the mediastinum and before the right pleural cavity was entered, two small arteries were found, one going toward the left and the other toward the right sequestered segments; these arteries were divided. No venous return was identified on the right side. A left lower lobe lobectomy was completed.

The patient recovered very well, with excellent clinical improvement, and returned to normal life. The pathological report showed bilateral pulmonary sequestration with acute and chronic infection and cavitory lesions on both sides. The connecting tunnel was composed of a central bronchus surrounded by pulmonary tissue and was covered by pleura; it also showed inflammatory changes. Computed tomographic scan 5 months later proved no residual pathological findings.

Comment

Bilateral pulmonary sequestration is a rare abnormality. Only 6 well-documented cases have been reported [5]. One was found in the autopsy of an infant. Two other patients had a resection of the symptomatic side only. The other 3 cases [5-7], only 1 of which had bilateral symptoms [6], were resected by staged bilateral thoracotomies. The pathology reports of these 3 cases were consistent with intralobar pulmonary sequestration.

Fig 1. Computed tomographic scan of chest with bilateral pulmonary lesions consistent with bilateral pulmonary sequestration and possible bridging tunnel.

The most common cause of morbidity in intralobar sequestration is infection resulting from the air passage that may develop between the normal lung parenchyma and the sequestered area. All authors mentioned agree that even asymptomatic sequestration should be resected to prevent infection. Once infection occurs, a major resec-

Fig 2. Angiogram demonstrating arterial supply from abdominal aorta to left sequestered segment (1), and from thoracic aorta (2) to the right sequestered segment (3) as well as the left sequestered segment (4).

Fig 3. Origin of connecting tunnel on left lower lobe (1). Connecting tunnel and sequestered segment (2) on right lower lobe were brought behind the heart (3) and through the mediastinum (4) into the left pleural cavity.

tion such as a lobectomy may be necessary, instead of a lesser resection such as a segmentectomy or wedge resection. Other causes of morbidity are massive bleeding [7] and the occurrence of tumors in the sequestered area [8].

Finally, our case clearly supports the advice of Roe and associates [7] and Juettner and colleagues [5] that staged bilateral thoracotomies are the approach indicated for the treatment of bilateral pulmonary sequestration. Median sternotomy would not have enabled us to resect the connecting tunnel.

We gratefully acknowledge the collaboration of Dr Jacob Groopman of the Pulmonary Department and Dr David Bryk of the Radiology Department at Maimonides Medical Center.

Giant Hamartoma of the Lung With a High Production of Carbohydrate Antigen 19-9

Kan Okabayashi, MD, Masafumi Hiratsuka, MD, Yuuji Noda, MD, Takeshi Hanagiri, MD, Tetsuya Mitsudomi, MD, Takayuki Shirakusa, MD, and Takahiko Kasai, MD

Second Department of Surgery and First Department of Pathology, School of Medicine, University of Occupational and Environmental Health, Japan, Kitakyusyu, Japan

A rare case of a giant pulmonary hamartoma with a high production of carbohydrate antigen (CA) 19-9 is presented. A 43-year-old woman with complaints of cough, fever, and chest pain was diagnosed as having a posterior mediastinal tumor with pneumonia. The serum CA 19-9 level was high. A thoracotomy revealed an intrapulmonary solid mass with a histologic diagnosis of cartilagi-

nous hamartoma with no evidence of malignancy. The CA 19-9 concentration in the mucus of the tumor was high, and postoperatively the serum CA 19-9 level returned to normal. The CA 19-9 could be immunohistochemically demonstrated on the surface of the tumor.

(*Ann Thorac Surg* 1993;55:511-3)

Carbohydrate antigen (CA) 19-9 is an antigen that was originally found on the surface of colon cancer cells detected by murine monoclonal antibody [1]. It is a clinically well-known tumor marker for diagnosis of gas-

trointestinal and pancreatic malignancies. Recently there have been some reports on elevation of CA 19-9 level in nonmalignant respiratory diseases [2, 3], such as bronchogenic cyst, intralobar sequestration, idiopathic pulmonary

fibrosis, and bronchial asthma. Here we report a case of giant hamartoma of the lung with a high level of CA 19-9 in both the serum and the secreted mucus.

A 43-year-old woman, who visited a private physician with complaints of productive cough, fever, and left chest pain, underwent a chest roentgenogram, which revealed an abnormal mass shadow in her left lung. She was referred to our hospital for further evaluation. Chest roentgenograms showed a large tumor with an infiltration in the left lower lung field (Fig 1). A physical examination revealed no abnormalities but diminished breath sounds over the left lower lobe. Laboratory tests revealed mild leukocytosis ($10.6 \times 10^9/L$ [$10,600/\mu L$]) and an elevated level of C-reactive protein ($>6+$). The serum CA 19-9 level was 460.0 U/mL (normal, <37.0 U/mL), the Sialyl Lewis X-i level was 66.4 U/mL (normal, <38.0 U/mL) but levels

of carcinoembryonic antigen and α -fetoprotein were within normal range. Administration of cephalosporin resulted in an improvement of the symptoms and in a decrease in the serum CA 19-9 and Sialyl Lewis X-i levels (126.3 and 37.7 U/mL, respectively). Nuclear magnetic resonance imaging of the chest demonstrated a large tumor with a well-defined margin (Fig 2). The presumptive diagnosis was a posterior mediastinal teratoma or a neurogenic tumor.

A thoracotomy revealed the tumor to be an intrapulmonary solid mass, and a left lower lobectomy was performed. The resected tumor ($9 \times 9 \times 8.7$ cm) was gyrus-shaped and cartilaginously hard, and weighed 576 g (without the lung tissue) with some viscous fluid in it. The CA 19-9 concentration in the mucus was 532,960 U/mL. Histologic examination showed chondromatous hamartoma with no evidence of malignancy. To see which

A

B

Fig 3. (A) Histologic examination revealing that this tumor is made of cartilage and epithelium without any malignant component. Pathologic diagnosis was chondromatous hamartoma. (Hematoxylin and eosin, $\times 20$ before 50% reduction.) (B) Immunoperoxidase staining with anti-CA 19-9 monoclonal antibody. The columnar epithelial cells lining the mesenchymal tissue give a positive reaction for CA 19-9. ($\times 200$ before 50% reduction.)

component of the tumor produced CA 19-9, we examined the localization of CA 19-9 immunohistochemically by the avidin-biotin-peroxidase complex method [4]. The CA 19-9 was demonstrated in some epithelial cells of the hamartoma (Fig 3). The postoperative course was uneventful, and the patient's serum CA 19-9 level returned quickly to the normal range. She has been in good health since this episode, with a normal serum CA 19-9 level.

Comment

Hamartoma is a common benign pulmonary tumor that generally occurs in adults. Most hamartomas are asymptomatic and are found at the peripheral lung parenchyma. Many resected hamartomas are around 2.5 cm in diameter, and only 12 cases have been reported in Japan to be more than 6 cm. It is generally easy to make a diagnosis of hamartoma when typical mottled calcification scattered throughout a discrete, smooth-margined mass is seen with normal surrounding lung [5]. However, in some cases it is quite difficult to distinguish hamartomas from pulmonary malignancies. Although the present case had almost all the radiographic characteristics, we never suspected a hamartoma because there was no room for normal lung tissue between lung and chest wall by computed tomography and nuclear magnetic resonance imaging, and because the serum CA 19-9 level was high.

Carbohydrate antigen 19-9 is a common tumor marker that is mainly present in gastrointestinal or pancreatic malignancies. A small amount of CA 19-9 is also present in normal cells, such as those of pancreatic duct, biliary duct, salivary gland ducts, and prostate and bronchial glands. It is certain that the hamartoma of this patient produces CA 19-9 because (1) no gastrointestinal or pancreatic problems were found perioperatively, (2) the serum CA 19-9 level returned to normal postoperatively, (3) mucus of the tumor contained a high concentration of CA 19-9, and (4) immunoperoxidase staining with anti-CA

19-9 monoclonal antibody could show strongly positive epithelial cells.

The term *hamartoma*, derived from the Greek words meaning "error" and "tumor," was proposed by Albrecht in 1904. Although originally it was thought to represent a malformation rather than a neoplastic disease, several investigators have suggested that the epithelial and the mesenchymal components, or the mesenchymal components alone, might be neoplastic [6, 7]. Recently Fletcher and associates [8] have demonstrated the neoplastic feature of the mesenchymal component, whereas epithelial cells appeared to be reactive, by an immunohistochemical/cytogenetic approach. In the present case, it is uncertain whether the lining epithelium rich in CA 19-9 production was neoplastic or reactive. Further research about CA 19-9 and pulmonary hamartoma may lead to resolution of this biphasic tumor.

Coronary Revascularization in a Patient With Porcelain Aorta and Calcified Great Vessels

Kevin D. Accola, MD, and Ellis L. Jones, MD

Division of Cardio-Thoracic Surgery, Joseph B. Whitehead Department of Surgery, Emory University School of Medicine, Atlanta, Georgia

Calcification of the aorta and great vessels in coronary artery bypass patients remains a challenging dilemma for the surgeon regarding bypass technique, choice of conduit, and available location of proximal anastomotic sites. Internal mammary artery flow may be inadequate, and the risk of systemic emboli from a diseased aorta is substantial. We report a case of a 69-year-old diabetic patient with a porcelain aorta extending into the aortic

arch and great vessels who was revascularized using an altered anastomotic technique of right coronary artery endarterectomy for proximal anastomosis of vein grafts. Intraoperative echocardiographic evaluation of the aorta and arch was beneficial in determining extent of calcification.

(*Ann Thorac Surg* 1993;55:514-5)

Extensive calcification of the ascending aorta, transverse arch, and the arch vessels is an infrequent but alarming finding during performance of coronary artery bypass grafting. The discovery of "porcelain aorta" requires technical changes in cardiopulmonary bypass as well as in revascularization techniques. Prior reports have discussed a "no-touch technique" using arterial conduits only and hypothermic fibrillatory arrest, use of arch vessels for proximal anastomoses, and even aortic endarterectomy in dealing with this problem [1, 2]. A technique that uses endarterectomy of the proximal right coronary artery (RCA) with vein graft insertion at this level is the subject of this report. Intraoperative echocardiography also proved extremely helpful in management of this difficult problem.

A 69-year-old diabetic woman with severe triple-vessel coronary artery disease underwent routine coronary revascularization. Intraoperative palpation of the aorta revealed severe calcification of the aorta, arch, and innominate origin. Intraoperative transesophageal and epicardial echocardiography was performed before cardiopulmonary bypass and demonstrated circumferential calcification of the ascending and descending aorta with extension well into the innominate artery (Fig 1).

The patient's femoral artery was cannulated, and she was placed on femoral-right atrial bypass and cooled to 22°C. Left ventricular venting was performed through the right superior pulmonary vein. During cooling the left internal mammary artery (IMA) was prepared and found to have adequate flow. The right IMA was not used because of its small size and the severe diabetic state of the patient. The greater saphenous vein provided adequate additional conduit. Under hypothermic fibrillatory

arrest the left IMA was anastomosed end-to-side to the left anterior descending artery. No sequential IMA anastomoses were done because of the diminutive size of the mammary artery. Distal saphenous vein anastomoses were performed to the posterior descending artery, mid-obtuse marginal artery, and a small diagonal branch of the left anterior descending artery. The proximal RCA was totally occluded, but palpation of its proximal portion revealed it to be soft. It was opened and endarterectomy performed back into the aorta. The posterior descending artery vein graft was anastomosed to the endarterectomized proximal RCA, and the remaining two vein grafts were brought off this graft in end-to-side fashion (Fig 2). Postoperatively the patient did well, and arteriography on the eighth postoperative day revealed good flow through the vein grafts. The saphenous vein graft to the small diagonal branch was occluded.

Comment

Intraoperative discovery of severe aortic and arch disease presents a challenging dilemma but an opportunity for creativity. Often these patients have severe generalized vascular disease as well as difficult coronary anatomy. Various options have been reported in the literature, as well as a few nonreported anecdotal cases requiring closure of the patient and aborting revascularization. Suma [1] recently reported a "no-touch technique" using arterial conduits and fibrillatory arrest. In his report of 3 patients, all men, a successful result was obtained. Our case differed in that the patient was a small, brittle diabetic woman with a previous abdominal operation. We

thought that complete arterial conduit usage was not an option and would have unnecessarily prolonged the operative procedure. The left IMA was not adequate in diameter to be used as a proximal anastomotic site or for sequential grafting as recommended by others [3]. Hypothermic fibrillatory arrest worked well using the recommendations of Akins [4]: maintaining a high perfusion pressure near 80 mm Hg and left ventricular venting.

Because of the circumferential and inclusive nature of the aortic calcification, we did not believe it would be a safe alternative to resect a portion of the aorta with application of a pericardial or prosthetic patch for a proximal anastomotic site as discussed by Robicsek and Rubinstein [5].

Because the anterior portion of the proximal RCA was easily accessible, this vessel was opened approximately 2 cm from the aortic ostia and endarterectomized. It proved to be of generous size and, therefore, was used as the proximal anastomotic site. The remaining vein grafts were then anastomosed to the posterior descending artery vein graft (see Fig 2). Postoperatively, coronary angiography was repeated and revealed excellent flow through the patent vein grafts.

This case report describes an alternate method of revascularization for difficult patients in whom a porcelain aorta and substantial arch and great vessel disease are discovered at operation.

Malignant Melanoma Metastatic to the Esophagus

Airton Schneider, MD, Nael Martini, MD, and Michael E. Burt, MD, PhD

Thoracic Service, Department of Surgery, Memorial Sloan-Kettering Cancer Center, New York, New York

Malignant melanoma metastatic to the esophagus, as the only evidence of disease, is rare. We present the only known case treated at our institution and review 10 other cases reported in the world's literature. Of 11 patients (including ours) with melanoma metastasizing to the

esophagus and no other known disease, no patient survived 1 year. With this dismal prognosis, the goal of therapy in these patients must be palliation of dysphagia.

(*Ann Thorac Surg* 1993;55:516-7)

Primary malignant melanoma of the esophagus is uncommon, the reported prevalence varying from less than 0.1% to 0.5% of all esophageal malignant tumors [1]. Metastatic involvement of the esophagus by melanoma, as the only clinical evidence of disease, is even less common. We were able to find only 10 reported cases since 1895 in a review of the world's literature [2-9]. Here we report a case seen at our institution.

A 37-year-old man had resection of Clark's level IV melanoma of the upper back, and left axillary dissection, in September 1983. All lymph nodes as well as margins of resection were negative for tumor. In November 1983, he noted progressive dysphagia to solids. Barium swallow was performed and revealed a polypoid mass defect in the distal one third of the esophagus. Biopsy was done and interpreted as metastatic melanoma. Computed tomographic scan of the brain, chest, and abdomen and radionuclide bone scan showed no evidence of other metastatic disease. In December 1983, the patient underwent an esophagogastrectomy by the Ivor-Lewis approach. Exploration of the abdomen revealed no evidence of nodal or liver involvement. During the thoracic esophageal dissection, enlarged periesophageal lymph nodes were found and removed with the specimen. The patient was discharged 2 weeks after operation swallowing solids. Pathologic interpretation was malignant melanoma metastatic to esophageal muscle wall and submucosa with overlying ulceration, negative proximal and distal margins of resection, and melanoma metastatic to one of three periesophageal and ten of 19 perigastric lymph nodes. He did well until October 1984, when dysphagia recurred. He died in November 1984 of diffuse metastatic disease.

Comment

Although metastases to distant sites from primary malignant melanoma are very common, there are only a few case reports of melanoma metastatic to the esophagus as the only evidence of disease [2-9].

Allen and Spitz [10] in 1949 established the criteria for the diagnosis of primary versus metastatic melanoma. Primary tumors originate from the basal layer of the esophageal mucosa, which shows conspicuous junctional changes such as are seen in malignant melanoma and junctional nevi of the skin. In melanoma metastatic to the esophagus, the metastasis is usually submucosal and polypoid. The mucosa is usually normal or secondarily ulcerated and lacks the junctional changes seen in primary esophageal melanoma.

In the 10 reported cases in the literature of melanoma metastatic to the esophagus (with no other sites of disease), no patient survived greater than 10 months. All patients eventually developed widespread distant disease and died (Table 1).

To evaluate the impact of resection in these patients, the data from our patient and the 10 from the literature were analyzed by the Kaplan-Meier method (Fig 1). As demonstrated in Figure 1, the prognosis for patients with metastasis to the esophagus from malignant melanoma, even as the only site of disease, is dismal. No patient survived greater than 11 months, with a median survival

Fig 1. Actuarial 5-year survival (Kaplan-Meier method) and resection status of 11 patients with melanoma metastatic to the esophagus (p value by log-rank analysis).

of only 5 months for the entire series. However, the patients who were treated by resection survived significantly longer.

Although review of the literature yielded only 11 patients (including the one we report here) with malignant melanoma metastatic to the esophagus as the only site of disease, a few observations seem apparent: (1) metastasis to the esophagus, even though apparently the only site of disease, is a harbinger of disseminated disease; (2) once patients present with a metastasis to the esophagus, the prognosis is grave; and (3) local therapy appears to offer a slight survival advantage. With these observations in mind, certain guidelines for treatment are apparent: (1) esophagogastrectomy may be warranted in selected pa-

tients; (2) palliation of symptoms, particularly dysphagia, is the goal; and (3) better chemotherapeutic regimens are sorely needed to prolong life.

Currently, we would recommend esophageal dilation, laser resection, or an endoesophageal prosthesis as the preferred palliation for these patients. Esophagectomy may be warranted for select patients with good performance status.

Primary Hemangiopericytoma Presenting as a Pancoast Tumor

Karen M. Chong, MD, Stuart C. Lennox, FRCS, and Mary N. Sheppard, MRCPATH

Departments of Lung Pathology and Cardiothoracic Surgery, Royal Brompton National Heart and Lung Hospital, London, England

An intrathoracic extrapulmonary hemangiopericytoma presenting as a Pancoast's tumor, an unusual association, is presented.

(*Ann Thorac Surg* 1993;55:518-9)

A 53-year-old woman was admitted to the Royal Brompton Hospital with a 14-month history of left shoulder pain radiating down her arm. A previous chest roentgenogram was reported as normal 1 year before. At presentation a repeat chest roentgenogram showed a shadow at the extreme apex of the left lung with destruction of the second rib. She had a Horner's syndrome but no obvious muscle wasting. A computed tomograph showed, in addition, involvement of the second vertebral body and spinal end of the second left rib (Fig 1). All other investigations were normal.

At thoracotomy the tumor was in the apex outside the pleura, involving the second rib and infiltrating the vertebral body. The lung was not involved. The bulk of the tumor was excised, and after a normal postoperative recovery the patient was referred to the Royal Marsden Hospital for radiotherapy. She was given a dose of 60 Gy over a period of 6 weeks. When seen 2 years later she was pain free without evidence of recurrence.

Macroscopic analysis of the resected specimen revealed a smooth, encapsulated mass measuring $6 \times 4 \times 2$ cm with attached soft tissue and part of the left second rib which was infiltrated by tumor. The cut surface was smooth, soft, and pale brown and surrounded the rib. Microscopic examination showed round and spindle cells with pale pleomorphic nuclei. These cells surrounded slitlike vascular spaces giving a staghorn appearance to the vessels as typically seen in hemangiopericytoma (Fig 2).

Reticulin staining delineated the subendothelial basal lamina and surrounded small groups of cells (Fig 2, insert). Desmin, leukocyte common, and keratin markers were negative. The tumor cells were immunoreactive for vimentin. Anti-factor VIII-related antigen delineated normal endothelial cells, which lined the sinusoidal vascular spaces. Tumor cells extended beyond the tumor capsule, and there was vascular invasion. The mitotic count was 3

to 5 per 10 high-power fields. Electron microscopy showed that a minority of tumor cells were rich in fine filaments and the majority had an incomplete basal lamina, features compatible with hemangiopericytoma. There was no evidence of any other type of differentiation at the electron microscopic level.

Comment

The light microscopic, immunohistochemical, and electron microscopic features of this patient's tumor are typical of hemangiopericytoma [1]. Hemangiopericytomas are rare tumors that arise in soft tissue and can infiltrate bone. The most common sites of origin are the thigh and pelvic peritoneum [2]. More than 60 primary hemangiopericytomas have been described in the lung, but they are very rare outside the lung within the thorax [3, 4]. A collective study in 1964 [5] described 10 cases arising in the upper part of the thorax, mainly in the mediastinum. None were said to cause Pancoast's syndrome, although 1 patient had Horner's syndrome. No histology was demonstrated. Six cases proved malignant, whereas the remaining four were localized and encapsulated. Since then two further cases have been reported [6]. Both originated from an intercostal space and appeared malignant. The tumor in our patient originated in the second intercostal space; as it showed mitotic activity, vascular invasion, infiltration of a rib, and extension outside the capsule, it was considered malignant [3]. Surgical excision followed by radiotherapy appears to be the best treatment [5], and our patient was symptom free at 2 years.

Pancoast's syndrome is now often interpreted liberally. In 1932 Pancoast [7] introduced the term *superior sulcus tumor* to describe a tumor occurring "at a definite location at the thoracic inlet," and with a roentgenographic appearance showing "a small homogenous shadow at the extreme apex" associated with "more or less rib destruction and often vertebral infiltration." He pointed out that these patients had a "constant and characteristic clinical phenomena of pain in the eighth cervical and first and second thoracic trunk distribution . . . and Horner's syndrome." He stated that these tumors should not be confused with tumors arising at the apex of the lung.

Most tumors described as causing Pancoast's syndrome have been primary carcinomas of the lung, but others have included mesothelioma, Hodgkin's lymphoma, multiple myeloma, thyroid carcinoma, and metastatic tumors

Accepted for publication April 23, 1992.

Fig 1. Computed tomographic scan of left apex showing destruction of second rib and erosion of vertebral body (arrow).

[8]. Nonneoplastic causes are rare and include tuberculosis, fungal infection, and hydatid disease [8].

The interesting feature of this patient is that she so clearly follows the pattern described by Pancoast in 1932. Pancoast thought that the behavior of these tumors was atypical for lung carcinoma because they lacked metastases to other sites as is common in lung tumors. All his cases had a fatal outcome with local disease infiltration. He postulated "a lack of origin from the lung, pleura, ribs or mediastinum" and suggested that the origin was possibly from some extrapulmonary structure. This case of hemangiopericytoma clearly fulfills Pancoast's criteria of a superior sulcus tumor. In addition, the use of resection followed by radiotherapy gave good results with prolonged survival.

Fig 2. Section of tumor showing spindle cells surrounding slitlike (staghorn) vascular spaces ($\times 150$ before 50% reduction). Insert shows a reticulin stain with outlining of the subendothelial basement membrane and individual cells surrounded by fibers.

Surgical Repair of Aorto–Right Ventricular Tunnel in an Infant

Todd K. Rosengart, MD, Dierk A. Redel, MD, and Jaroslav F. Stark, MD

The Harley Street Clinic, London, England, and Department of Pediatric Cardiology, University of Bonn, Bonn, Germany

A rare case of aorta to right ventricle tunnel with associated pulmonary stenosis was corrected on cardiopulmonary bypass in a 3-month-old infant. Both the aortic and ventricular openings were closed with a patch. Although the repair was successful and the child was discharged from the hospital, septicemia developed and she died later. Early repair of this defect is recommended.

(Ann Thorac Surg 1993;55:520–2)

Aortoventricular tunnel (AVT) is a rare congenital malformation presenting as aortic insufficiency and severe congestive heart failure in the neonate or young infant.

In some 50 previously reported cases of AVT, communication was between the right coronary sinus and the left ventricle [1–5]. Two articles report 1 case each of aorto–right ventricular tunnel: 1 in a neonate who died 6 hours after birth and another in a 10-year-old child who was successfully operated on [6, 7]. Here we report correction of aorto–right ventricular tunnel in an infant.

The patient was born after a normal pregnancy at full term to nonconsanguineous parents with no clinically significant past family history. Birth weight was 4.3 kg. A murmur was noted at birth, and a diagnosis of “ruptured sinus of Valsalva aneurysm” was made by echocardiography on the third day of life at the University Children’s Hospital, Bonn. Symptoms of congestive heart failure were treated with digoxin and diuretics, and the patient was discharged home. Recurrent lung and urinary tract infections subsequently developed. Cardiac catheterization at the age of 5 days confirmed the diagnosis of aortoventricular communication (Fig 1). In addition, a valvular right ventricular outflow tract gradient of 60 mm Hg was noted. At the age of 3 months the patient was transferred to London for semiurgent operation. Bacterial pharyngitis precipitated severe congestive failure and led to intubation and ventilatory support of the patient.

On admission, a 4/6 systolic murmur was noted. Pulses were “bounding.” The child was pale and gray, tachypneic (100 breaths/min) and tachycardic. Electrocardiography showed right ventricular hypertrophy. Chest roentgenogram revealed severe cardiomegaly and pulmo-

nary plethora. Oxygen was administered through nasal prongs, central venous and arterial monitoring was instituted, and the child’s condition was stabilized. Operation was organized for the following morning, October 1, 1991. Through a midline sternotomy, the thymus was partially excised and the pericardium was opened. The heart was grossly enlarged. A communication was noted arising from behind the right side of the dilated aortic root, passing leftward toward the base of the heart. The aorta and the right atrium were cannulated, and standard hypothermic cardiopulmonary bypass was instituted. The aorta was cross-clamped, and crystalloid cardioplegia (20 mg/kg) was administered into the root of the aorta while the “tunnel” was occluded with forceps.

A standard oblique aortotomy was performed. The aortic valve appeared to be rotated about 90 degrees clockwise, so that the left coronary artery was situated anterior to its normal position. The left coronary artery was probed, but the right coronary artery was not visualized. Dilatation of the aortic root at the juncture of the right and noncoronary sinuses was noted. A supraannular orifice approximately 1 cm in diameter communicated from the base of the dilatation to the extracardiac chamber. It was closed with a Gore-Tex (W. L. Gore & Assoc, Flagstaff, AZ) patch and 6-0 Prolene (Ethicon, Somerville, NJ). Care was taken not to distort the aortic valve leaflets or the left coronary orifice.

The right ventricular outflow tract was then opened with a short oblique incision. A large, posterior infundibular “defect,” approximately equal in diameter to the pulmonary valve orifice, was noted. This orifice appeared to be lined with normal ventricular endocardium. No evidence of inflammatory changes or ruptured aneurysm was seen. This defect, which was the ventricular opening of the tunnel, was closed with a Gore-Tex patch and running 5-0 Prolene suture, followed by aortotomy closure.

The ventricular wall was extremely thick, measuring about 3 cm. The muscle was pale and showed some fibrotic changes. Some muscle bands were excised, and the anterior wall of the right ventricle was thinned. The pulmonary valve was stenotic, and commissurotomy was performed. The aortic clamp was then removed and the patient was completely rewarmed. After ventriculotomy closure, bypass was discontinued and protamine given.

The hemodynamics were satisfactory, with an arterial systemic pressure of 90 mm Hg and a right atrial mean pressure of 6 mm Hg. Arterial blood gas analysis showed a pH of 7.37, carbon dioxide tension of 22 mm Hg, and oxygen tension of 452 mm Hg. During rewarming severe

Fig 1. (A) Injection into the ascending aorta (AO) demonstrates the tunnel (T), which empties into the right ventricular outflow (RVO). (B) Lateral projection of the injection into the ascending aorta shows that the tunnel connects the aorta to the right ventricular outflow.

arrhythmias developed, including complete heart block and recurrent ventricular fibrillation. This instability continued after the bypass had been discontinued. Eventually the child returned to normal sinus rhythm. Recurrent ventricular fibrillation was controlled with a lignocaine infusion. The chest was splinted and the skin closed with a silicone rubber membrane, leaving the sternum opened.

Because of the severe ventricular hypertrophy and poor preoperative ventricular function, the patient was kept ventilated on a regimen of dobutamine drip, digoxin, and diuretics. The arrhythmias resolved and the chest was closed on the third postoperative day. Subsequently line sepsis developed, which responded well to the appropriate antibiotics. Administration of catecholamines was

discontinued very gradually because the left ventricular function remained impaired. The child was extubated on day 13. The final Doppler echocardiography showed much improved biventricular function. There was a residual gradient from the right ventricle to the pulmonary artery of 36 mm Hg. No aortic insufficiency was noted. C-reactive protein level returned to normal, and the white blood cell count before discharge was $13.9 \times 10^9/L$. The child was discharged home to Germany 20 days after operation on furosemide, 3 mg daily; captopril, 0.5 mg three times a day; and digoxin.

Five days after discharge the child had a fever and was readmitted to the University Children's Hospital, Bonn. Two-dimensional echocardiography showed vegetations on the patch. The child's condition became toxic and, despite intensive antibiotic therapy and resuscitation, she died 10 days after admission. Permission for postmortem examination was not granted by the family.

Comment

The clinical and pathological features of AVT considerably overlap those of ruptured sinus of Valsalva aneurysm. They have even been grouped together as "aorto-cardiac fistula" [8]. It has been suggested that AVT may represent in utero rupture of a sinus of Valsalva aneurysm [9, 10]. Aortoventricular tunnel often presents in the first few days of life [2], whereas ruptured aneurysm of the sinus of Valsalva is more common in the second to fourth decade of life [8]. The AVT is of the same consistency and thickness as the aortic wall and is associated with an externally visible structure that may even be seen as an extracardiac bulge on a chest roentgenogram [1]. The AVT then passes through the septum behind the right ventricular infundibulum to enter the left ventricle. In rare cases such as the one presented here, the AVT enters the right ventricle. In contrast, ruptured aneurysm of the sinus of Valsalva is a thin-walled, narrow outpouching running an entirely intracardiac course to the cardiac chamber. The entrance is most often in the form of a perforated wind-sock [8]. To distinguish between AVT and ruptured sinus of Valsalva aneurysm may not be clinically, echocardiographically, or angiographically possible. It is, however, not important, as both conditions should be treated surgically.

We believe that the treatment should be undertaken in the neonatal period or as soon as the diagnosis is made. The clinical course of our patient would support this recommendation. Although the patient's heart failure was initially controlled, severe ventricular hypertrophy subsequently developed. That was most likely the cause of severe postoperative arrhythmias and initially impaired ventricular function. In addition, the patient suffered several infective episodes, which are always more difficult to treat in an infant in severe heart failure. Whether the final infection was related to these episodes or to the last episode of postoperative line sepsis, or whether it was entirely independent of these is open to discussion.

In conclusion, we have presented an infant with rare aorta to right ventricle tunnel. Although the repair was successful, the child died later in severe septic shock. We recommend early surgical repair for patients with AVT.

Sequestration of the Left Coronary Artery From the Aorta

Marius J. Swart, MB, ChB, John A. Odell, FRCS(Edin), and Richard C. Fraser, FCP(SA)

Department of Cardio-thoracic Surgery and Cardiology, University of Cape Town Medical School, Cape Town, South Africa

A patient with the left coronary artery isolated from the ascending aorta is discussed. This is the seventh case described and the third diagnosed preoperatively. In contrast to other patients she had predominant aortic incompetence and was much older (52 years compared with the other patients, all younger than 25 years). She also had two angiograms demonstrating progressive iso-

lation of the coronary artery with time. The patient was managed by aortic valve replacement. It is our belief that the condition is acquired and resulted from fusion of the free edge of the aortic valve leaflet to the supravalar ridge secondary to an inflammatory process.

(*Ann Thorac Surg* 1993;55:523-4)

A 45-year-old woman was admitted initially in 1983 with dyspnea and chest pain. There was a history of rheumatic fever as a child and previous treatment for pulmonary tuberculosis. Investigations including cardiac catheterization confirmed aortic valve regurgitation and almost complete isolation of the left coronary artery, except for a small communication, from the aorta. Surgical correction was advised but was declined by the patient.

In 1990, when 52 years old, she was readmitted with similar symptoms. She was undistressed with no features of infective endocarditis. The pulse was regular and the blood pressure was 150/60 mm Hg. The apex of the heart was laterally displaced. The first heart sound was soft with an ejection click present. A systolic ejection murmur and a soft early diastolic murmur were heard at the base of the heart and along the left sternal border.

The electrocardiogram demonstrated sinus rhythm, right bundle-branch block, left-axis deviation, and signs of left atrial enlargement. The cardiac silhouette was enlarged on chest roentgenogram.

A 10-mm Hg peak to peak gradient across the aortic valve was measured at catheterization. The valve was not calcified, and the aortic root was dilated. Severe aortic regurgitation was evident, but the ventricle contracted well and was not dilated. The left coronary artery could not be entered. The right coronary artery was a widely patent dominant vessel. A very large conal branch arising from the proximal right coronary artery filled the unobstructed left coronary artery system. Retrograde filling of the left coronary artery showed delineation of a rudimentary left valvar sinus (Fig 1).

During cardiopulmonary bypass with moderate hypothermia and crystalloid cardioplegic arrest the anatomy was defined through a transverse aortotomy. Large right and noncoronary cusps with slightly thickened edges

were found. In the position of the left coronary cusp a domed structure, which appeared to be thickened valve tissue, was completely fused with the supravalar ridge (Fig 2). No egress of blood or cardioplegia could be demonstrated. An incision exposed a valve sinus with a small but patent left coronary artery ostium at the base. No thrombus was present. The valve was replaced with a 25-mm tilting disc prosthesis. Her postoperative course was uneventful.

Comment

Adhesions of the free edge of an aortic valve leaflet to the aortic wall have been well documented. However, this is mostly associated with supraaortic stenosis. In fact, cusp abnormalities were present in more than a third of cases reported in a review of supraaortic stenosis by Rastelli and associates [1]. Underdevelopment of the left coronary cusp was noticed most commonly, but partial cusp adhesions were seen frequently by Flaker and colleagues [2].

Complete isolation of the coronary cusp and the coronary artery in patients with supraaortic stenosis has been described four times [3-6]. Two left and two right coronary cusps were involved. Only one [5] was recognized preoperatively on angiography, the other three being noted at autopsy.

Two further cases have been described [7, 8]. Waxman and co-workers [7] reported isolation of the left coronary artery in a patient with aortic stenosis and regurgitation. A 16-year-old girl presented with syncope and chest pain. There was no history of an inflammatory process. Cardiac catheterization revealed moderate aortic valve regurgitation and a 20-mm Hg gradient across the aortic valve. An isolated left coronary sinus filled retrogradely through the right coronary artery and collaterals. The indication for operation was angina, and at operation the cusp was freed. Follow-up examination and catheterization were normal. Although it was not histologically proven, Waxman and co-workers speculated that their case was a forme fruste of supravalar aortic stenosis.

Fig 1. Catheterization of right coronary artery demonstrating filling of the left coronary system and left sinus of Valsalva through a large caval branch.

The question still remains whether isolation of the left coronary ostium is acquired or congenital. The absence of initial signs and the thickened cusps tend toward a gradual inflammatory process involving the valve cusps with adhesions to the aortic wall, but also may be ascribed to a congenital abnormality of the leaflet tissue. In two reports [7, 8] the consensus leaned toward a developmental abnormality. We believe that in our patient it was

Fig 2. Surgeon's view of domed structure in left sinus of Valsalva.

probably acquired. A heart murmur was noticed 25 years before, and she became symptomatic late in life. There is a history of rheumatic fever as a child, although in isolated aortic valve disease one should also consider nonrheumatic aortic root disease. Over a 7-year period the left coronary ostium progressed from a small communication between the aortic root and left coronary sinus to a complete seal. Unfortunately, the first angiogram was inadvertently destroyed, but the catheterization report is adamant in the description of the left coronary artery filling retrogradely from the right and communicating with the aortic root. One of us (R.F.) performed the first angiogram. Varying degrees of adherence of valve cusps to the aortic wall have been described [2]. Histologic examination of the thickened cusps in our case was unhelpful.

Under normal circumstances one would expect a blind-ending vessel to thrombose and obliterate, but compression of the sinus during systole with to-and-fro movement of blood in and out of the sinus during the cardiac cycle probably prevented stasis formation. This was noticed by Waxman and co-workers [7] as well.

Adhesions of aortic valve cusps are common in the rare condition of supra-ventricular aortic stenosis. Complete isolation has been described in 4 patients with supra-ventricular aortic stenosis. This phenomenon was also seen in a patient with quadricuspid aortic valve and could represent a congenital defect [8]. Although the patient of Waxman and co-workers had associated aortic regurgitation, operation was for angina and syncope. Our patient was operated on for pure regurgitation with late onset of symptoms and signs, and no evidence of stenosis. A preoperative diagnosis was possible and a relatively simple operation gave good results.

Angiosarcoma of the Heart Causing Cardiac Rupture: A Rare Cause of Hemopericardium

Sunil K. Ohri, FRCS, Petros Nihoyannopoulos, MD, Kenneth M. Taylor, MD, and Bruce E. Keogh, MD

Cardiothoracic Unit, Department of Surgery, Hammersmith Hospital, Royal Postgraduate Medical School, London, England

Cardiac rupture as a complication of primary cardiac tumors has rarely been reported in the literature. The diagnosis is difficult to establish preoperatively, but echocardiography may provide the best assessment of cardiac damage. We found a loculated pericardial effu-

sion on two-dimensional echocardiography, a finding that has been documented in two of the previous four case reports. A case of right atrial rupture is reported with review of other cases from the literature.

(Ann Thorac Surg 1993;55:525-8)

Angiosarcomas are the most prevalent primary malignant cardiac tumors, accounting for 20% of all cardiac malignancies [1]. The presentation of angiosarcoma is usually late, when the tumor begins to limit cardiac output by mechanical obstruction. However, most tumors are locally invasive, so local resection or transplantation may still be a therapeutic option [2]. Cardiac rupture remains a rare complication of primary heart tumors, but cases of cardiac rupture secondary to metastatic involvement of the heart by other malignancies has been described [3]. We report a case of right atrial rupture secondary to a primary cardiac angiosarcoma that was not diagnosed preoperatively despite echocardiography and computed tomographic scanning.

A 47-year-old man presented to his local hospital with a 5-week history of breathlessness and dull chest pain. On admission he was found to have a swinging pyrexia of up to 38°C. On examination, he had no palpable lymph nodes, but was clinically anemic. Cardiovascular examination found the signs of cardiac tamponade: pulse, 120/minute; blood pressure, 110/60 mm Hg with a pulsus paradoxus of 15 mm Hg; jugular venous pressure, 7 cm H₂O, cardiac sounds faint but normal, and the apex beat shifted to the midaxillary line. Respiratory, abdominal, and neurologic examinations were normal. Hematologic tests revealed a normochromic normocytic anemia of 9.4 g/dL (normal, 13.0 to 18.0 g/dL), a mild neutrophilia of $10 \times 10^5/L$ (normal, 2.0 to $7.5 \times 10^5/L$), and a normal platelet count. A chest roentgenogram found a large heart with a globular cardiac silhouette. A two-dimensional echocardiogram showed a loculated effusion.

After 10 days as an inpatient he was discharged home because of reduction in his symptoms and a repeat echocardiogram that had shown a substantial decrease in the size of his effusion from 4 cm to 1 cm. However, he returned to his local hospital 3 weeks later after an

episode of collapse. On readmission, echocardiography was unchanged. Two pericardiocenteses via the sub-xiphisternal approach were unsuccessful in obtaining pericardial fluid. He was transferred to another hospital. A computed tomographic scan showed a poorly defined mass lying anteriorly over the heart in the superior part of the mediastinum; it was not possible to discern if this was a loculated part of the pericardial cavity, but there was no pericardial effusion inferiorly. Metastatic lesions were also noted in the lungs. He was urgently transferred to the Hammersmith Hospital for the establishment of a tissue diagnosis. His clinical state had seriously deteriorated, and he now had intractable dyspnea. A two-dimensional echocardiogram with color Doppler flow imaging showed a large, loculated pericardial effusion surrounding the right ventricular free wall and base of the heart. Intracardiac anatomy was normal, but there was an ill-defined mass surrounding the right ventricular inflow tract, constricting and compressing the tricuspid annulus and extending both anteriorly and posteriorly, invading the right ventricular walls and right atrium (Fig 1). Color Doppler flow failed to identify a communication between the right atrium and the pericardial cavity. Right ventricular function was poor, with diastolic compression of the right ventricular outflow tract; left ventricular function was normal.

He was submitted for operation. At median sternotomy, a hemopericardium was evident. On opening the pericardium a large volume of blood was lost and the systolic blood pressure fell to 30 mm Hg. A hole was found in the right atrium at the junction of the superior vena cava, which was approximately 2 cm in length. Hemorrhage was controlled by placing a digit in the rupture, and the patient was transfused blood and colloid. The pressure returned to the preoperative level of 90 mm Hg systolic. On assessment, the tumor was invading most of the right atrium and was involving the right ventricle and the superior and inferior venae cavae. The edges of the right atrial rupture were diaphanous and

Fig 1. Right ventricular inflow tract view showing a large mass compressing the tricuspid annulus. The right ventricular free wall was somewhat thickened and homogeneously echogenic with global hypokinesia suggestive of myocardial infiltration by the tumor. (RA = right atrium; RV = right ventricle; T = tumor.)

involved by tumor. The majority of the pericardial cavity was obliterated by tumor and adhesions, except for an area around the free wall of the atrium. Blood had been escaping from the right atrium and entering a loculation within the pericardial cavity. A biopsy of the tumor was performed. In view of the advanced stage of the disease, localized resection under cardiopulmonary bypass was not undertaken. The walls of the atrium would not have accepted a Dacron patch, and the available pericardium was also involved with disease. The atrial rupture was enlarged digitally and the pericardium closed, thus creating a neo-right atrial appendage. A postoperative two-dimensional echocardiogram showed that the right ventricular outflow tract was no longer compressed in diastole, and clinically this was correlated with a reduction in his dyspnea. He was assessed by the oncology team, who concluded that chemotherapy and radiotherapy were inappropriate given the nature of the tumor and its advanced stage. Histologic examination of operative biopsy specimens found the tumor to be an angiosarcoma.

The patient died 22 days postoperatively of advancement of his cardiac disease. This was confirmed by autopsy, which found an angiosarcoma originating near the annulus of the tricuspid valve and extending to invade the right ventricle, most of the right atrium, the superior vena cava, and pulmonary artery. The tumor had exten-

sively invaded the pericardium, and metastatic nodules were identified in both lungs but in no other part of the body.

Comment

Cardiac rupture due to angiosarcoma is extremely rare; 4 other cases, all involving the right atrium, have been reported in the literature to date [4-7]. The presentations (Table 1) have been diverse, from nonproductive cough and chest pain [4] to bilateral pneumothoraces [5], supraventricular tachyarrhythmia [6], and bloody pleural effusion [7]. In our patient, breathlessness was the main complaint on presentation. This was due to the size of the tumor and obstruction of the right atrium and ventricle as demonstrated by echocardiography. Of the 4 previously reported patients only 2 survived to have the diagnosis confirmed at operation, and only in 1 patient reported by Satou and associates [7] was the diagnosis truly established by preoperative investigations. In this patient blood was seen leaving the right atrium and circulating within the pericardial cavity on color Doppler and contrast two-dimensional echocardiography. In our patient, using similar scanning techniques, we were unable to find a rupture point preoperatively. The most frequently reported echocardiographic finding in cases of cardiac rupture has been a loculated pericardial effusion. This echocardiographic sign was found in the present case and in 2 of the 4 previously reported cases (see Table 1). The loculations may be a desmoplastic response to the tumor, inflammation, and adhesion formation secondary to neoplastic infiltration or a response of the pericardium to the chronic exposure of blood and clot.

Because of the late presentation of patients with these tumors, up to 80% of cases have pulmonary metastases [1]. Nevertheless, this does not preclude surgical intervention. If the tumor can be locally excised, then this may still produce good palliation of symptoms. Heart or heart-lung transplantation may be considered for those patients with disease limited to the heart or those with metastases limited to the lungs [8]. None of these surgical options was appropriate for our patient, but postoperatively his dyspnea was substantially improved. We can only postulate that this was a result of creating a larger defect in the right atrial wall, which allowed the blood to circulate freely within the pericardial cavity without compressing or tamponading the right ventricular outflow; this improvement was demonstrated by postoperative echocardiography.

Anecdotal reports of long-term survival are present in the literature with adjuvant chemotherapy or radiotherapy, but no definitive studies are available due the rarity of the malignancy. Recently, Putman and associates [2] retrospectively reviewed their 25-year experience with cardiac sarcomas, which included 7 angiosarcomas, but could find no improvement in survival using doxorubicin-based chemotherapy.

REVIEW OF RECENT BOOKS

John Gibbon and His Heart-Lung Machine

By Ada Romaine-Davis

Philadelphia, University of Pennsylvania Press, 1991

251 pp, illustrated, \$37.95

Reviewed by John C. Myers, MD

Recent graduates of cardiothoracic surgical training programs are fortunate to have used and taken for granted technology in cardiopulmonary bypass that allows for the completion of cardiac surgical procedures with lower operative mortality than many noncardiac thoracic operations. *John Gibbon and His Heart-Lung Machine* offers a personal look at a true pioneer and visionary whose work paved the way to the potential complacency of today's resident.

This well-written monograph ranges from anecdotes of Dr Gibbon's childhood to a detailed discussion of his animal and initial human experiences with his invention. From his early clinical exposure to pulmonary embolism as a surgical resident and the wish to support these patients during embolectomy, to his methodical development of a reproducible machine, to successful correction of an atrial septal defect, this monograph chronicles Gibbon's successes and failures in a highly readable fashion.

This book is a welcome addition to the library of cardiothoracic surgeons, cardiac physiologists, and those interested in surgical history. Read it with pleasure.

Postcardiotomy LVAD Support and Transesophageal Echocardiography in a Child

Scott A. Scheinin, MD, Branislav Radovancevic, MD, David A. Ott, MD,
Michael R. Nihill, MD, Allison Cabalka, MD, and O. H. Frazier, MD

Department of Cardiovascular Surgery, Texas Heart Institute, and Department of Pediatric Cardiology, Texas Children's Hospital, Houston, Texas

A case of postcardiotomy cardiogenic shock after repair of a congenital ventricular septal defect in a 5-year-old boy is reported. Mechanical circulatory support, instituted with a centrifugal left ventricular assist device, adequately supported the patient for 50 hours until recovery of native left ventricular function occurred.

Transesophageal echocardiography proved to be useful in assessment of left ventricular function, allowing for timely institution and withdrawal of mechanical circulatory support.

(Ann Thorac Surg 1993;55:529-31)

Extracorporeal mechanical circulatory assistance has become a viable option for adult patients with postcardiotomy cardiogenic shock that is refractory to pharmacologic support. Infants and small children who experience postoperative ventricular dysfunction, however, have fewer treatment options. For example, size constraints, as well as increased aortic compliance, render the intraaortic balloon pump ineffectual in young patients [1]. Recent reports [2, 3] have indicated encouraging results using venoarterial bypass with an extracorporeal membrane oxygenator; however, the procedure for instituting support is labor intensive, and prolonged support is associated with major complications. We treated one of our pediatric patients who had postcardiotomy cardiogenic shock after repair of a congenital heart defect with an extracorporeal centrifugal ventricular assist device. Transesophageal echocardiography (TEE) was used to monitor left ventricular recovery, which enhanced the success of treatment.

A 5-year-old boy (20 kg) underwent surgical repair of a perimembranous ventricular septal defect. Preoperative examinations revealed a dilated left ventricle (end-diastolic dimension, 48 mm; shortening fraction, 0.38) and a redundant anterior leaflet of the tricuspid valve. Ventricular function was preserved (left ventricular pressure, 110/4 mm Hg; right ventricular pressure, 28/4 mm Hg). Pulmonary artery pressure was 28/10 mm Hg (mean, 16 mm Hg), and pulmonary artery wedge pressure was 8 mm Hg. Retrograde flow through the ventricular septal defect was causing tricuspid valvular dysfunction with a pulmonary-to-systemic blood flow ratio of 2:1. There was no evidence of aortic or pulmonary valve dysfunction.

At operation, total cardiopulmonary bypass was instituted with bicaval and aortic cannulation. The heart was

arrested with 15 mL/kg of standard Roe's cardioplegic solution at 6°C, and Dacron patch repair of the ventricular septal defect was accomplished (total ischemic time, 25 minutes). Attempts to wean the patient from cardiopulmonary bypass failed. Electrocardiography revealed a widened QRS complex and transitory third-degree heart block, and TEE revealed global left ventricular dysfunction with paradoxical septal motion. Air embolization to the coronary arteries was suspected and treated by briefly cross-clamping the aorta again and by providing inotropic support.

Despite maximal pharmacologic support and resumption of sinus rhythm, further attempts to wean the patient from bypass failed. Thus, mechanical circulatory support with a Bio-Medicus (BP50; Bio-Medicus, Minneapolis, MN) ventricular assist device was instituted. A 28F wire-reinforced right-angle cannula (Research Medical, Salt Lake City, UT) was inserted into the left atrium through the right superior pulmonary vein. Blood was returned to the ascending aorta through a 14F aortic cannula (Texas Medical Products, Houston, TX). Flow from the Bio-Medicus pump was maintained at 2 L/min (cardiac index, $2.6 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$), and the patient was weaned from bypass (total bypass time, 158 minutes), during which time TEE was used to gauge the degree of ventricular distention. No immediate cause for the ventricular dysfunction was apparent. Electrolytes within the cardioplegic solution were confirmed to be normal. The sternum was left open, and the skin was reapproximated with interrupted sutures.

During the next 24 hours, the patient's condition stabilized. Average pump flow was maintained at 2 L/min, and amrinone and nitroprusside were given to reduce afterload (left atrial pressure, 8 to 12 mm Hg). Postoperative bleeding was moderate, necessitating the transfusion of 3 units of packed red blood cells, 4 units of platelets, and 1 unit of fresh-frozen plasma during the first 24 hours of support. Mild hemolysis was present, as evidenced by a decrease in the plasma free hemoglobin level (from 34

Accepted for publication May 4, 1992.

Fig 1. Evidence of left ventricular recovery consisted of increasing pulse pressure and stabilization of filling pressure as pump flow decreased. The weaning process began at 40 hours after support had been instituted. (CVP = central venous pressure; LAP = left atrial pressure; PP = pulse pressure.)

mg/dL after 4 hours of pump support to 29 mg/dL after 24 hours). Transesophageal echocardiography on postoperative day 1 revealed slight improvement in ventricular wall motion, continued antero-septal hypokinesia, and paradoxical septal motion. In addition, the left ventricular cavity remained distended (43 mm). The next day, systemic pulse pressure increased to 40 mm Hg, which indicated ventricular recovery. Before the weaning process was begun, systemic heparinization was instituted (400 U/h). Pump flows were progressively decreased to 1 L/min, at which time mean arterial pressure ranged from 65 to 75 mm Hg, without an increase in left atrial or central venous pressures (Fig 1).

After approximately 50 hours of pump support, the patient was returned to the operating room for completion of the weaning process and removal of the device. Intraoperative TEE revealed improvement of left ventricular contractility and of septal dyskinesia. Mitral and tricuspid valve functions were normal. The cannulas were removed, and the sternum was closed. The patient remained hemodynamically stable, and all pharmacologic support was stopped during the next 24 hours. No deterioration in renal or hepatic function was observed during circulatory support. The patient was weaned from mechanical ventilatory support the day after circulatory support had been discontinued. Repeat TEE showed good posterior wall motion with minimal septal motion (shortening fraction, 0.29).

The remainder of the patient's postoperative course was uneventful. He was able to ambulate and progressively returned to his normal functional level. On postoperative day 7, echocardiography revealed no residual ventricular septal defect and a dilated left ventricle (end-diastolic dimension, 42 mm); however, left ventricular function was normal (estimated shortening fraction, 0.35). The patient was discharged from the hospital and prescribed digoxin, captopril, and furosemide. Three weeks after operation, echocardiography revealed a left ventricular end-diastolic dimension of 42 mm and a shortening

fraction of 0.38. Posterior wall motion was normal, but septal dyskinesia persisted.

Comment

Our case shows the feasibility of treating children who experience postcardiotomy cardiogenic shock with an extracorporeal mechanical circulatory support device. The 5-year-old boy in this case received adequate circulatory support for approximately 50 hours, which allowed time for left ventricular recovery. No major complications occurred during or after operation. Although mild hemolysis was observed after the operation, it was probably related to the prolonged cardiopulmonary bypass time, not to left ventricular assist device support. Follow-up 3 weeks after the patient was discharged revealed improved left ventricular function.

Use of ventricular assist devices in children has been limited. Matsuda and associates [4] reported using a paracorporeal, pneumatically driven ventricular assist device in 3 pediatric patients (ages, 3 to 10 years) who experienced postoperative cardiogenic shock after repair of congenital anomalies. Two patients died of multiorgan failure during circulatory support, and the third died of respiratory failure 20 days after being weaned from the device. Three other patients (ages, 9 to 11 months) who experienced postcardiotomy shock received left heart support (duration of support, 5 to 13 days) with a centrifugal pump and were weaned from support; however, they died of infectious or thromboembolic complications [5]. Frazier and colleagues [6] reported use of a centrifugal pump for left heart support as a bridge to transplantation in a 9-year-old boy.

The success of mechanical circulatory support in our patient can be partially attributed to TEE. The development of smaller endoscopic probes has made TEE a useful technique for diagnosing and characterizing congenital cardiac anomalies in pediatric patients [7]. In addition, TEE is useful for gauging intraoperative repair and monitoring myocardial function [8]. In our case, TEE allowed accurate and timely assessment of left ventricular function and recovery, which permitted expeditious weaning from extracorporeal circulatory support. We believe that timeliness was instrumental in preventing major complications.

Our case demonstrates that extracorporeal circulatory support can be used effectively to sustain a pediatric patient during postcardiotomy cardiogenic shock. With the timely removal of such support, complications can be minimized and the patient returned to a normal level of activity.

Notice From the American Board of Thoracic Surgery

The part I (written) examination will be held at the Hilton Executive Conference Center, Dallas Fort Worth Airport, Dallas, TX, on February 13, 1994. The closing date for registration is August 1, 1993.

To be admissible for the part II (oral) examination, a candidate must have successfully completed the part I (written) examination.

A candidate applying for admission to the certifying examination must fulfill all the requirements of the board in force at the time the application is received.

Please address all communications to the American Board of Thoracic Surgery, One Rotary Center, Suite 803, Evanston, IL 60201.

Warm Heart Surgery in Patients With Cold Autoimmune Disorders

Derek D. Muehrcke, MD, and David F. Torchiana, MD

Surgical Cardiovascular Unit, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

Continuous warm antegrade delivery of cardioplegia while maintaining systemic normothermia is a new method of performing coronary artery bypass grafting. It can be used to avoid the detrimental effects of hypothermia in patients with cold autoimmune disease.

(*Ann Thorac Surg* 1993;55:532-3)

Cryoglobulinemia is one of three primary cold autoimmune diseases. When patients with this disorder are cooled below a critical temperature, immunoglobulins precipitate in their serum [1]. This can cause systemic hyperviscosity, microvascular thrombosis, purpura, and progressive glomerulonephritis [1]. Current methods of performing cardiac operations on these patients require that serum immunoglobulins be removed by plasmapheresis preoperatively [2] or be flushed out of the coronary arteries by warm crystalloid cardioplegia before cold crystalloid cardioplegia is given [3, 4] or that operation be performed on the warm heart as it fibrillates without aortic cross-clamping [1]. We report the successful performance of a coronary bypass operation in a patient with documented cryoglobulinemia using systemic normothermia and continuous warm antegrade blood cardioplegia [5] in an effort to avoid the adverse effects of hypothermia. This technique is applicable to all cold autoimmune diseases.

A 69-year-old man with a 14-year history of angina (Canadian Heart Association classification IV) was admitted to our hospital with persistent anginal pain and electrocardiographic evidence of inferior myocardial ischemia. He received intravenous streptokinase therapy, and a myocardial infarction was documented with a total creatine kinase level of 4,000 U and a creatine kinase MB fraction of 500 U. Angina continued to occur at rest despite intravenous nitroglycerin therapy, oral β -blockers, and calcium-channel blockers. Cardiac catheterization revealed reduced left ventricular function and severe three-vessel coronary artery disease with 2+ mitral regurgitation. The day after angiography pain and tenderness in the legs developed, associated with a purpuric rash, which suggested a cutaneous vasculitis. Serum immune screening revealed the presence of cryoglobulins of the

immunoglobulin A- κ and immunoglobulin G families. A cryohematocrit was negative for hemagglutinins. Based on the patient's lower extremity rash and the finding of cryoimmunoglobulins in the serum, a diagnosis of primary cryoglobulinemia was made. The cryoglobulinemia crisis was thought to have been brought on by the cardiac catheterization, which used room temperature contrast agents. Because of persistent angina after a myocardial infarction associated with severe three-vessel disease, coronary artery bypass grafting was performed.

After median sternotomy and heparinization, the heart was cannulated through the ascending aorta and right atrium. The saline prime was recirculated through the heat exchanger at 37°C (Bard Membrane Oxygenator, Tewksbury, MA) to keep it from cooling before cardiopulmonary bypass was instituted. Bypass was instituted at normothermia using the technique described by Lichtenstein and associates [5]. With the heart empty and beating, a hyperkalemic blood cardioplegia solution was introduced into the root of the aorta at 37°C. The aorta was cross-clamped between the cardioplegia port and the aortic cannula. An initial arrest dose of 1,500 mL of high-potassium solution (potassium content, 20 mEq/L) was infused, followed by continuous low-potassium (potassium content, 7 mEq/L) blood cardioplegia into the aortic root and subsequently through vein grafts. Throughout the cross-clamp period, brief (5- to 10-minute) interruptions of cardioplegia administration occurred to facilitate the performance of the distal anastomoses.

Vein grafts were performed to the posterior descending artery and the circumflex marginal artery; the left internal mammary artery was used to bypass the left anterior descending artery. Proximal anastomoses were done with the aortic cross-clamp still in place. After removal of the cross-clamp, normal sinus rhythm returned spontaneously without need for defibrillation. Urine output on bypass was excellent. Because of transient worsening of mitral regurgitation the patient was placed on 5 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ of dopamine and weaned from cardiopulmonary bypass after 93 minutes. There were no electrocardiographic or enzymatic signs of perioperative myocardial infarction, and his renal function remained normal. There were no other signs of an agglutinin reaction in the postoperative period. He was discharged home on postoperative day 15, with his hospitalization prolonged by paroxysmal atrial fibrillation, which had also been a problem preoperatively.

Comment

The primary cold autoimmune diseases include cold hemagglutinin disease, paroxysmal cold hemoglobinuria, and cryoglobulinemia. This uncommon group of immunologic disorders is characterized by the abnormal production of autoantibodies, usually of the immunoglobulin M class but occasionally of the immunoglobulin G and immunoglobulin A classes. They are directed against the I antigen or related antigens on erythrocytes of autologous blood. Cold agglutinins have a range of thermally mediated immunologic activity referred to as the thermal amplitude. Below this temperature antigen-antibody complexes form, resulting in hemagglutination, hemolysis, or precipitation from solution [1].

A variety of cold-mediated problems have been encountered during cardiac operations in patients with cold autoimmune disease. Systemic hypothermia during cardiac operations may be associated with massive hemagglutination, widespread microvascular thrombosis, immediate or delayed hemolysis, and immune complex or hemolytic nephritis causing acute or chronic renal failure. Coronary perfusion with cold blood or iced potassium cardioplegic solutions may cause intracoronary hemagglutination with coronary thrombosis, subendocardial ischemia, and, possibly, myocardial infarction.

Several methods have been employed to avoid these detrimental effects of hypothermia in both the systemic and intracoronary circulations. Preoperative plasmapheresis has been used to temporarily reduce cold agglutinin titers [2]. Also described is a combination of mild systemic

hypothermia and coronary washout with normothermic cardioplegia during aortic cross-clamping, immediately followed by hypothermic cardioplegia [3, 4]. Finally, the combination of systemic normothermia and continuous coronary perfusion of a fibrillating heart without aortic cross-clamping has been proposed as an effective method of dealing with this disorder [1].

The use of warm cardiac surgery as described by Lichtenstein and associates [5] avoids the problems associated with cold autoimmune disease because the patients are not exposed to the precipitating factor, hypothermia. Our case illustrates the successful use of this technique in a patient with cryoglobulinemia, but patients with other cold autoimmune diseases may likewise benefit.

Use of a Heat Exchanger to Prevent Hypothermia During Thoracic and Thoracoabdominal Aneurysm Repairs

Kevin W. Ireland, BSN, CCP, David M. Follette, MD, John Iguidbashian, MD, Marc E. Pollock, MD, Rick Yoshikawa, BS, CCP, Jim Sam, BS, CCP, and Herbert A. Berkoff, MD

Division of Cardiothoracic Surgery, University of California, Davis Medical Center, Sacramento, California

Hypothermia is a common unplanned occurrence in many patients undergoing repair of thoracic and thoracoabdominal aneurysms. Many undesirable side effects of hypothermia have been documented, including decreased cardiac output, conduction abnormalities, and blood coagulopathies. We have developed a simple system that incorporates a Sci-Med Biotherm heat exchanger into our left heart bypass circuit. This provides us with the ability to actively rewarm the patient safely and

efficiently. This study looks at 16 consecutive patients undergoing repair of thoracic or thoracoabdominal aneurysms. In the 9 patients in whom the heat exchanger was used, there were no adverse effects related to the heat exchanger. All patients had significantly higher temperatures at the conclusion of the procedure than the 7 patients in whom the heat exchanger was not used.

(*Ann Thorac Surg* 1993;55:534-7)

In 1984, the Bio-Medicus centrifugal pump was first reported as a useful adjunct in the repair of traumatic rupture of the aorta [1]. Since that time, left heart bypass with the use of the Bio-Medicus pump has been widely used during the repair of descending thoracic and thoracoabdominal aneurysms [2-4]. During this same period, somatosensory evoked potentials [5], cerebrospinal fluid pressure monitoring [6], upper and lower extremity pressure monitoring, and Swan-Ganz catheters to measure cardiac filling pressures and cardiac output during the procedure are now also used at most centers. The placement of these sophisticated monitoring catheters takes time; although heating blankets have been used, the patients' temperatures often drop before the actual incision is made. In addition, the operation may require a thoracoabdominal incision, which also results in heat loss [7]. Although blood warming devices and heating blankets are used these have been ineffective in consistently maintaining patients' normal temperature. Because of our concern over the decreased cardiac output [8], conduction abnormalities [9], arrhythmias, and coagulopathies [10] that are associated with serious hypothermia, we thought that the ability to maintain or rewarm a patient during left heart bypass would be a useful adjunct to the procedure.

This report describes our technique in 16 consecutive patients undergoing repair of thoracic or thoracoabdominal aneurysms with or without the use of a heat exchanger (Table 1).

Technique

After patients are placed on the operating table, a right heart catheter is passed through the right internal jugular vein to monitor cardiac output and pulmonary capillary wedge pressure. Arterial pressure monitoring catheters are then placed in the right radial and right dorsalis pedis vessels for upper and lower extremity pressure monitoring. When anesthesia has been induced, a double-lumen endotracheal tube is placed and positioned appropriately. Somatosensory evoked potential monitoring is done routinely, and the appropriate electrodes are positioned. Cerebrospinal fluid pressure monitoring is accomplished with lumbar puncture.

A standard left posterior lateral thoracotomy or thoracoabdominal incision is then made, and the left common femoral artery is isolated for perfusion, as is the left atrial appendage. The Sci-Med Biotherm heat exchanger (Sci-Med Life Systems, Minneapolis, MN) is incorporated into our standard tubing pack, which is a Carmeda-coated left heart bypass system (Medtronic Blood Systems, Anaheim, CA) using a BioMedicus centrifugal pump (Medtronic Blood Systems) (Fig 1). The system is primed by gravity using sterile technique, ensuring that it is bubble-free. Varying sizes of wire-reinforced Carmeda-coated perfusion cannulas (Research Medical, Salt Lake City, UT; and Medtronic Blood Systems) are used depending on the atrial size. For distal aortic perfusion or femoral artery perfusion, varying sizes of Carmeda-coated arterial cannulas are used as well; the prime is 500 mL.

Before bypass, the patients are heparinized with 5,000 units of heparin to obtain an activated clotting time of approximately 180 seconds. Flows generally range between 3 and 4 L/min, and distal perfusion pressure is

maintained between 50 and 60 mm Hg. Cerebrospinal fluid pressure monitoring is accomplished in an attempt to maintain the pressure between 10 and 15 cm H₂O. Body temperature is monitored by placement of a Foley catheter with a thermistor probe. Temperature measurements were made on all 16 patients when they entered the room, before bypass, at the end of bypass, and postoperatively (Table 2). We set the water bath temperature at 34°C while the surgical repair was being completed. This was done to possibly add additional spinal cord protection. The temperature, however, was not allowed to go to less than 31°C because of the potential for cardiac irritability.

At the conclusion of the arterial repair we begin to actively rewarm the patient. Bypass is discontinued when the bladder temperature reaches 37.4° ± 0.2°C, and the appropriate dose of protamine is administered. Blood from the circuit is then aspirated into a Cell Saver (Haemonetics, Braintree, MA) device, processed, and returned to the patient. This technique has been used in 9 consecutive patients undergoing thoracic or thoracoabdominal aneurysm repair. We have retrospectively compared these patients with 7 patients who underwent repair without a heat exchanger (see Table 1).

Results

The outcome and complications for these 16 patients are detailed in Tables 3 and 4. No patient died within 30 days of operation. There are 2 patients who died during their period of hospitalization. Both of these patients were in group 1, in which the heat exchanger was used. These 2 patients had undergone repair of complex thoracoabdominal aneurysms. These were the only patients in whom renal failure, ischemic bowel, hepatic failure, and sepsis developed, all of which occurred late in their postoperative course. One patient in this group required reexploration for bleeding. The bleeding vessel was controlled at the time of reoperation.

In the patients without the heat exchanger, there was only one major complication. Paresis of the lower extremities developed in this patient. There were no neurologic complications in those patients with the heat exchanger. There were no serious intraoperative arrhythmias in either group.

We also looked at blood product use in the two groups.

Patient populations were not similar, however. Group 1 had a large percentage of elective thoracoabdominal repairs (7 of 9 patients), whereas group 2 tended to be patients undergoing emergency repair of thoracic aneurysms (5 of 7 patients). Table 4 illustrates perioperative blood product use and postoperative losses in our patients. The numbers are too small and the groups too diverse to make statistical comparisons.

We did, however, closely evaluate the effectiveness of the heat exchanger in terms of rewarming the patients. Table 2 illustrates the temperatures in our patients. In those patients in whom the heat exchanger was used, the temperature was lowered to 34.1° ± 0.2°C on bypass, and all patients were rewarmed to 37.4° ± 0.2°C before bypass was completed. These patients maintained their temperature before transfer to the surgical intensive care unit. In contrast, the temperatures of patients in whom the heat exchanger was not used tended to drift down to 35.8° ± 0.2°C before bypass, drop an average of 0.9° ± 0.2°C during bypass, and remain significantly lower before transfer to the surgical intensive care unit (35.1° ± 0.3°C). This has illustrated to us the effectiveness of the Sci-Med heat exchanger in preventing hypothermia during the repair of thoracic and thoracoabdominal aneurysms.

Comment

Hypothermia, defined as a core temperature less than 36°C, is an everyday unplanned occurrence in most operating rooms [7]. Many factors precipitate hypothermia. They include cold ambient operating room temperatures, general anesthesia with central nervous system depression, decreased metabolic rate and vasodilatation, exposed sedated patients, and surgical procedures requiring large open exposures [7]. Trauma patients with traumatic tear of the aorta are especially prone to hypothermia. In these patients, the time required to extricate, transport, and work-up the patient all lead to varying degrees of cooling. In addition, these patients often receive large volumes of resuscitative fluids that are not prewarmed. Therefore hypothermia, before entering the operating room, can be quite severe.

In our series of patients, the temperature before institution of left heart bypass averaged $34.2^\circ \pm 0.3^\circ\text{C}$. After bypass the two groups showed a significant difference in temperature before the completion of the operation. Hypothermia affects each organ system differently. The cardiovascular system begins to show changes at 32°C with a decrease in cardiac output [8]. At 30°C the cardiac output is 40% of normal and sinus bradycardia is seen. Conduction abnormalities also begin to appear at this particular temperature. Ventricular fibrillation is common as the temperature approaches 28°C, especially in the presence of an ischemic myocardium or in patients with

coronary artery disease [9]. We did not see serious intra-operative arrhythmias in our patients, possibly because the temperature in both groups was not less than 34°C.

The blood's coagulation processes are enzymatic reactions that are dependent on temperature. Ferrara and associates [10] demonstrated in their review of 45 trauma patients requiring massive transfusion that patients with a core temperature less than 34°C had a statistically significant increase in coagulopathy and mortality. This occurred despite adequate blood, plasma and platelet administration. They felt the avoidance or correction of hypothermia seemed to be the most important factor in preventing or correcting these coagulopathies.

Others have shown that hypothermia at 32°C results in

Cryo = cryoprecipitate; FFP = fresh frozen plasma; Plt = platelets; PRBC = packed red blood cells.

a significant prolongation of partial thromboplastin time, a significant decrease in platelet counts and platelet aggregation, prolonged onset times, and a decreased rate of Sonoclot formation, as well as a shortened euglobulin lysis time [11, 12]. All these changes returned to normal by rewarming, and the changes were most likely due to decreased function of the clotting factors. Hypothermia appears to make the blood hypocoagulable and cause platelet sequestration in the liver and release of plasminogen activators in the fibrinolytic system [11, 12]. Although we could not show significant changes with respect to blood product use in our patients, this is likely secondary to the small numbers of patients and the diversity of our groups.

Hypothermia also leads to peripheral vasoconstriction. This increased afterload can cause significant stress on the myocardium, as well as severe arterial hypertension [9]. This may threaten the integrity of the multiple anastomoses required during thoracoabdominal procedures.

The spinal cord's sensitivity to ischemia is well known and documented [13]. A number of factors may protect the cord during operation. We have used spinal cord evoked potential monitoring to detect serious ischemia. We have also measured cerebrospinal fluid, pressure and we withdraw fluid when necessary. Hypothermia may also have a protective effect on the spinal cord during the period of aortic clamping. For this reason, our patients were kept cold until the clamp was removed. Although the numbers are small, we did not have any patients in this group who suffered any adverse neurologic sequelae.

To reverse the hypothermia that occurs during the repair of thoracic and thoracoabdominal aneurysms, we have incorporated the Sci-Med Biotherm heat exchanger in our Carmeda-coated left heart bypass tubing packings. This has allowed our patients to leave the operating room with a normal temperature. Before we began using this system, patients were routinely hypothermic when they were returned to the surgical intensive care unit. Using this system in 9 consecutive patients, we have seen no adverse reactions.

In conclusion, unplanned hypothermia is a common occurrence in patients undergoing the surgical repair of thoracic and thoracoabdominal aneurysms. Many undesirable side effects of hypothermia have been well documented, all of which can increase the patient's operative

morbidity and potential mortality. Use of the Sci-Med Biotherm heat exchanger, in conjunction with left heart bypass, provides the ability to actively rewarm patients safely and efficiently.

Selective Jugular Cannulation for Safer Retrograde Cerebral Perfusion

Hiroshi Okamoto, MD, Kosei Sato, MD, Akio Matsuura, MD, Yutaka Ogawa, MD, Teiji Asakura, MD, Motoaki Hoshino, MD, Akira Seki, MD, Toshio Abe, MD, and Kenzo Yasuura, MD

Division of Thoracic Surgery, Yokkaichi Municipal Hospital, and Department of Thoracic Surgery, Nagoya University School of Medicine, Yokkaichi, Japan

Hypothermic retrograde cerebral perfusion is a new technique for protecting the brain. Satisfactory cerebral protection should be possible even for periods of retrograde perfusion greater than 60 minutes. However, there are some concerns that functioning venous valves at the jugular-subclavian junction may impede retrograde flow to the brain and consequently cerebral protection may

not be adequate. To overcome this obstacle, we have developed an easy and safe technique of selective jugular cannulation through the right atrium using a central venous catheter and a guidewire. We have employed this technique successfully in 15 patients who underwent operation on the aortic arch.

(Ann Thorac Surg 1993;55:538-40)

Profound hypothermic circulatory arrest has been widely used during aortic arch operations since it was introduced by Griep and associates [1]. Although the maximum duration of circulatory arrest without sequelae has not been clearly defined, neurological damage becomes evident if the ischemic interval exceeds 60 minutes [2]. To overcome this disadvantage, we developed a technique of retrograde total body perfusion through both venae cavae to protect the brain and other systemic organs [3]. We have employed this technique in 34 patients undergoing operations on the aortic arch. Good cerebral protection has been obtained by this method in most patients, including 2 in whom periods of retrograde perfusion exceeded 100 minutes [3]. In first 19 patients retrograde perfusion was performed through conventional caval cannulas, but one of these patients sustained serious neurological damage despite a relatively short duration of retrograde perfusion. Judging from the observation that only her head and neck were completely free of edema just after the operation, it is presumed that a competent valve at the venous angle was impeding retrograde flow through the superior vena cava to the brain. To achieve adequate cerebral protection during retrograde perfusion through the venae cavae, we have developed a new technique that employs a cavoatrial cannula inserted selectively into the internal jugular vein beyond the valve at the venous angle and have applied this technique in the last 15 patients.

Technique

At the induction of anesthesia, a Swan-Ganz catheter and a 7F or 8F central venous catheter are inserted into the

internal jugular vein for pressure monitoring and drug infusion, and the latter is advanced about 20 cm to locate the catheter tip in the right atrium when retrograde perfusion is performed. The operation is performed using cardiopulmonary bypass with bicaval venous cannulation through the right atrium and common femoral arterial cannulation. Total cardiopulmonary bypass is established, and systemic cooling is commenced. The ascending aorta is then cross-clamped and cold blood cardioplegic solution is infused retrogradely through the coronary sinus. After the proximal ascending aorta is opened to assess the inner aortic wall and the aortic valve, proximal aortic repair is performed. The completion of proximal aortic repair usually coincides with the endpoint of core cooling with the rectal temperature reaching less than 20°C. At this point, pump perfusion is temporarily discontinued, the superior vena caval cannula is removed, and both venae cavae are snared. The "reversed over-the-wire catheter cannulation" technique is now described in detail. A short atriotomy is performed in the upper portion of the right atrium, and the tip of a central venous catheter is identified (Fig 1A). A 0.35-inch guidewire 150 cm in length passing in a 24F or 26F venous cannula is inserted into the central venous catheter tip and advanced to the neck in the reverse direction (Fig 1B). Holding and tensing each end of the guidewire both in the operative field and at the anesthesiologist's side, the snare around the superior vena cava is released temporarily and the venous cannula is advanced over the central venous catheter selectively into the internal jugular vein beyond the venous valve at the venous angle (Fig 1C). The position of the cannula tip can be easily confirmed by palpation of the neck by the anesthesiologist if it is located in the internal jugular vein. The guidewire is pulled out by the anesthesiologist, and the venous cannula is connected to the extracorporeal circuit (Fig 1D). Usually the

Fig 1. Essential steps for selective jugular cannulation: (A) A 7F or 8F central venous catheter is inserted into the right atrium through the internal jugular vein at the induction of anesthesia. When proximal repair is accomplished and the rectal temperature falls to less than 20°C, pump perfusion is temporarily discontinued and the superior vena caval cannula is removed. A short atriotomy is performed, and a 0.35-inch guidewire 150 cm in length passing in a 24F or 26F venous cannula is inserted into the central venous catheter tip. (B) The guidewire is advanced to the neck in the reverse direction. (C) A venous cannula is advanced over the central venous catheter selectively into the internal jugular vein beyond the venous valve at the venous angle. (D) The guidewire is pulled out by the anesthesiologist, the superior vena caval cannula is connected to the cardiopulmonary bypass circuit, and the central venous catheter is connected to a transducer to monitor the perfusion pressure.

above-mentioned procedures require only a few minutes. The aortic clamp is removed and retrograde perfusion is initiated; open distal anastomosis is then performed (Fig 2).

Comment

Profound hypothermic circulatory arrest makes it unnecessary to apply the aortic clamp and consequently can afford a bloodless operative field and simplifies the operative procedure on the aortic arch. However, many authors agree that the risk of neurologic sequelae becomes significant if the period of the circulatory arrest exceeds 45 to 60 minutes in humans when the nasopharyngeal temperature is 15 to 18°C [1, 2], although a longer time is occasionally required to accomplish distal aortic repairs.

Retrograde perfusion through the superior vena cava was first clinically employed to evacuate air in the systemic circulation during cardiopulmonary bypass by Mills and Ochsner in 1980 [4]. Lemole and associates [5] applied this method to implanting an intraluminal sutureless graft for acute aortic dissection in 1982. Ueda and associates [6] employed this technique to extend the safe duration of hypothermic circulatory arrest during the surgical treatment of the aortic arch aneurysm in earnest. Furthermore, we have developed a technique of continuous retrograde total body perfusion to protect not only the brain through the superior vena cava, but also the abdominal visceral organs through the inferior vena cava [3]. However, there are some concerns that venous valves may impede retrograde flow to the brain and consequently cerebral protection may not be adequate whether the perfusion is performed only through the superior vena cava or through both venae cavae.

Venous valves in the internal jugular vein are present at the venous angle (jugular-subclavian junction) in 80% to 90% of humans. Most of these valves are vestigial and

Fig 2. The aortic clamp is removed and retrograde perfusion is initiated; open distal anastomosis is then performed. (○→ oxygenated blood perfusing systemic organs; ■→ deoxygenated blood returning from the body; ▤→ cold blood cardioplegia.)

incompetent, but in some patients (10% to 20%) they are functioning and may interfere with retrograde flow through the superior vena cava to the brain [7]. Because there are no valves in the internal jugular vein above the venous angle as well as in the intracranial sinuses, we believe that the superior vena caval cannula should be placed in the internal jugular vein beyond the venous valves at the venous angle to achieve adequate cerebral protection during hypothermic retrograde perfusion. Although selective cannulation into the internal jugular vein through the right atrium is difficult and could even be traumatic to thin and friable venous walls if it were attempted without a guide, the reversed over-the-wire catheter cannulation technique that we have described here enables selective cannulation to be done easily. This technique has proved to be safe and reproducible in 15 consecutive patients who underwent aortic arch operations since November 1991. This technique may provide more effective cerebral protection than simple retrograde perfusion through the superior vena cava.

Pericardioperitoneal Window

Nelson Ancalmo, MD, and John L. Ochsner, MD

Department of Surgery, Ochsner Clinic, Baton Rouge, Louisiana, and Ochsner Clinic and Alton Ochsner Medical Foundation, New Orleans, Louisiana

A technique to create a pericardial window is discussed. By creating a communication between the pericardial and peritoneal cavities, adequate drainage is obtained without the need for external draining systems. The technique is simple, easy to learn, and without serious complications.

(*Ann Thorac Surg* 1993;55:541-2)

The subxiphoid approach used to drain pericardial effusions has been described in the medical literature [1-4]. Modifications of this technique have also been presented [5, 6]. Most surgeons prefer this approach to the transthoracic window, because the subxiphoid approach is an easier operation with lower morbidity. The video-assisted thoracoscopic pericardial window, although requiring smaller incisions, still depends on the ability of the patient to sustain one-lung general anesthesia and to be positioned laterally.

The subxiphoid approach is performed through an upper midline incision with the patient in the supine

position under general or local anesthesia. The linea alba is divided, and the pericardium is exposed. After a window is created in the pericardial sac, the fluid is evacuated, and a drainage system is left in place to collect any reaccumulation of fluid. A disadvantage of this procedure is the inconvenience of having a tube inserted in the pericardium that may need to remain in place for several days. This may become uncomfortable for the patients, could prolong the hospital stay, and increases the chances of infection in the pericardial cavity through an open incision. A simple modification of this technique was described by Dabir and Warren in 1984 [7]. We believe it is a safe and useful method to drain pericardial effusions.

Technique

After the pericardial sac is exposed and the fluid is evacuated, the diaphragmatic surface of the pericardium is visualized, and an opening is created to join the pericardial and peritoneal cavities (Fig 1). The window is at least 2 × 2 cm; the cut edges of the pericardium,

Fig 1. (A) Insert showing the vertical subxiphoid incision. (B) The juxtaposition of the pericardial and peritoneal cavities is emphasized. The pericardium is opened through a vertical incision. (C) After the window is created, interrupted sutures are placed to hold all layers together and to ensure patency.

Accepted for publication Nov 12, 1992.

Address reprint requests to Dr Ancalmo, Ochsner Clinic of Baton Rouge, 16777 Medical Center Dr, Baton Rouge, LA 70816.

diaphragm, and peritoneum are sutured together with a few interrupted sutures. The dome of the liver prevents any abdominal viscera from herniating into the pericardial cavity, and the subdiaphragmatic recess acts as a collection chamber for the pericardial fluid. No external drains are necessary, and the linea alba, subcutaneous tissues, and skin are closed in the usual manner. Patients can be discharged as soon as their condition permits.

Comment

We have used this approach in 15 patients. Of these, 12 had a diagnosis of malignancy, and metastatic disease to the pericardium was suspected. The other 3 patients had effusions of undetermined cause. Because all cultures were negative, the effusions were classified as idiopathic. This simple modification is useful in the management of noninfectious pericardial effusions; adequate drainage was obtained, and no serious complications occurred related to the procedure.

In uremic pericardial effusions, it may be inadvisable to

create this communication in patients undergoing peritoneal dialysis.

Preparation of Autologous Fibrin Glue From Pericardial Blood

Henrik K. Kjaergard, MD, Ulla S. Weis-Fogh, MSc, and Jens J. Thiis, MD

Department of Cardiothoracic Surgery, Rigshospitalet, and Institute for Experimental Research in Surgery, University of Copenhagen, Copenhagen, Denmark.

To salvage patients' blood and improve hemostasis in cardiac operations, autologous fibrin glue was prepared in a new way by means of ethanol from pericardial blood. The yield from 44 mL of blood was 2.1 ± 0.7 mL (mean $\pm$ standard deviation) of fibrinogen concentrate with a concentration of 25.1 ± 7.5 mg/mL; 2.7 mL of

two-component glue was obtained after the addition of thrombin solution. The glue has the advantages of safety from transmission of viral diseases and from immunologic reactions.

(*Ann Thorac Surg* 1993;55:543-4)

Hemostasis and salvage of patients' blood is crucial in modern operations to avoid blood transfusion. Autologous fibrin glue is a hemostatic agent that can be prepared by means of ethanol [1-3]. To salvage patients' blood and improve hemostasis in cardiac operations, this study was designed to test the possible preparation of autologous fibrin glue from pericardial and mediastinal blood.

Patients and Methods

Twenty-eight patients admitted for elective coronary artery bypass grafting were included in this study. The 24 men and 4 women participating had a mean age of 61 years (range, 30 to 71 years), a mean weight of 77.9 kg (range, 46 to 108 kg), and a mean hemoglobin level of 8.8 g/L (range, 7.3 to 10.1 g/L).

After sternotomy but before the pump suction could be used, 44 mL of pericardial and mediastinal blood was drawn into a syringe containing 6 mL of heparin (20 IU/mL) and citrate (129 mmol/L) as anticoagulant. The plasma was separated from the blood cells by centrifugation, and the fibrinogen was precipitated with ethanol (99%) by incubation at 0°C for one-half hour. The preparation was completed in a closed system to ensure sterility [1-3]. The fibrinogen concentration in the concentrated solution was measured by the method described by Weis-Fogh [1]. The second component of the glue contained thrombin, 1,200 IU/mL, calcium chloride, 100 mmol/L, and aprotinin, 6,000 KIU/mL.

Results

The mean volume of fibrinogen concentrate was 2.1 ± 0.7 mL (mean $\pm$ standard deviation) with a concentration of 25.1 ± 7.5 mg/mL. After 0.3 parts of thrombin solution was added, the total volume of two-component fibrin glue

was 2.7 mL. The glue was sterile and could be prepared in less than 90 minutes.

Comment

A small volume of blood is wasted during opening and cannulation in cardiac operations before the pump suction can be used. In this study we were able to collect the blood from the pericardium and the mediastinum in a syringe containing anticoagulant, and to prepare fibrinogen concentrate from the blood. The outcome was a good yield of fibrin glue comparable with autologous glue prepared from venous blood by the same method (fibrinogen concentration, 28 mg/mL) [2, 3]. Autologous fibrin glue can be prepared in different ways [4-7]. Experimental data suggest that the glue's strength is related to the fibrinogen concentration [8]. Autologous fibrin glue prepared by means of ethanol is suitable for clinical use as a hemostatic agent and as a sealant of pulmonary air leak and of high-porosity vascular prostheses [2, 3]. Additionally it has the advantages of safety from transmission of viral diseases and immunologic reactions [1-3, 9]. Currently we are testing a new device with which sterile fibrinogen concentrate can be prepared in less than 30 minutes, making it more useful in acute operations.

Notice From the American Board of Thoracic Surgery

The American Board of Thoracic Surgery began its recertification process in 1984. Diplomates interested in participating in this examination should maintain a documented list of the operations they performed during the year prior to application for recertification. This practice review should consist of 1 year's consecutive major operative experiences. (If more than 100 cases occur in 1 year, only 100 need to be listed.) They should also keep a record of their attendance at approved postgraduate medical education activities for the 2 years prior to application. A minimum of 100 hours of approved CME activity is required.

In place of a cognitive examination, candidates for recertification will be required to complete both the general thoracic and cardiac portions of the SESATS IV syllabus (Self-Education/Self-Assessment in Thoracic Surgery). It is not necessary for candidates to purchase

SESATS IV booklets prior to applying for recertification. SESATS IV booklets will be forwarded to candidates after their applications have been accepted.

Diplomates whose 10-year certificates will expire in 1995 may begin the recertification process in 1993. This new certificate will be dated 10 years from the time of expiration of the original certificate. Recertification is also open to any diplomate with an unlimited certificate and will in no way affect the validity of the original certificate.

The deadline for submission of applications is May 1, 1993. A recertification brochure outlining the rules and requirements for recertification in thoracic surgery is available upon request from the American Board of Thoracic Surgery, One Rotary Center, Suite 803, Evanston, IL 60201.

Sinus of Valsalva Aneurysms and Application of Surgical Science to Their Repair

William L. Holman, MD

Division of Cardiothoracic Surgery, University of Alabama at Birmingham, Birmingham, Alabama

Congenital aneurysms located in the sinuses of Valsalva typically expand and may eventually rupture into the right atrium or ventricle. In 1957, Dr Lillehei and colleagues reported 3 patients who underwent successful repair of ruptured sinus of Valsalva aneurysms at the University of Minnesota. This achievement required an accurate understanding of the pathology and anatomy of

sinus of Valsalva aneurysms, as well as the successful application of surgical science to solve the problems posed by the repair of these aneurysms. Doctor Lillehei's article is a classic in the field of cardiothoracic surgery and is now reviewed 36 years after its publication.

(*Ann Thorac Surg* 1993;55:545-51)

Fig 1. Doctor Lillehei and colleagues published their case reports in *The Annals of Surgery* in 1957 under this title head. (Reprinted from *Ann Surg* 1957;146:459-72, by permission.)

In May 1957, Dr Lillehei and colleagues at the University of Minnesota presented 3 patients who had successful repair of ruptured sinus of Valsalva aneurysms to the annual meeting of the American Surgical Association. The article describing this experience (Fig 1) summarizes knowledge that was gained from observations of human pathology as well as experiments carried out in animals. The article is remarkable both for the quality and originality of its information, and merits review as a reminder of what can be accomplished by the application of surgical science to the solution of clinical problems.

Pathology of Ruptured Sinus of Valsalva Aneurysms

Although reports of sinus of Valsalva aneurysms published in the nineteenth century correctly described the relationship of the aneurysm sac to the right atrium and ventricle, they did not attempt to classify sinus of Valsalva aneurysms according to anatomic location, nor did they discern their congenital etiology. Maude Abbott first postulated that a congenital weakness of the aorta was the cause of sinus of Valsalva aneurysms in a series of observations published in 1919 [1]. In 1957, Edwards and Burchell [2] published photomicrographs (Fig 2) graphi-

cally confirming the deficiency of elastic and muscular tissue immediately above the annulus of the aortic valve that leads to the development of sinus of Valsalva aneurysms. Abbott [1] attributed sinus of Valsalva aneurysms to a developmental deficiency of the distal bulbar septum. This notion is supported by the frequent (30% to 60%) coexistence of ventricular septal defects and sinus of Valsalva aneurysms [3-5]. Moreover, the frequency of these aneurysms is highest in the right sinus of Valsalva, which abuts the largest region of the septum, although aneurysms have been reported to arise from all three sinuses.

The relationship of the aortic root and sinus of Valsalva aneurysms to the cardiac chambers was beautifully illustrated in the 1949 article of Jones and Langley [6] (Fig 3). Jones and Langley described the possible paths of aneurysm expansion into the right heart; however, the classification system of Sakakibara and Konno [7] is the one most commonly used today to describe the location of sinus of Valsalva aneurysms. According to the nomenclature of Sakakibara and Konno, congenital sinus of Valsalva aneurysms types I through IV are defined according to the position of the aneurysm sac relative to the right or noncoronary aortic valve cusps. This position also determines which cardiac chamber (right atrium or right ventricle) is invaded by the expanding aneurysm.

An expanding sinus of Valsalva aneurysm may take on the appearance of a windsock (Fig 4), although this is not always the case. The fistulous communication that exists between the aorta and the right heart after rupture of a sinus of Valsalva aneurysm can produce acute symptoms of pain and dyspnea; however, 50% to 70% of patients experience slowly progressive symptoms or no symptoms [3-5]. An expanding but unruptured sinus of Valsalva aneurysm can also produce symptoms by obstruction (eg, right ventricular outflow tract obstruction), deformation (eg, left or right coronary ostial deformation with resultant myocardial ischemia) [8], or compression (eg, ventricular tachycardia due to compression of the ventricular septum) [9].

C

Fig 2. (A) Longitudinal section of a normal heart taken through the noncoronary sinus of Valsalva. (B) Longitudinal section of the heart demonstrating an aneurysm of the right sinus of Valsalva. (L.V. = left ventricle; R.A.L. = right aortic valve leaflet; R.V. = right ventricle). (C) Longitudinal section of the heart demonstrating a thin-walled sinus of Valsalva aneurysm protruding into the right atrium immediately above the tricuspid valve (Post. aortic cusp = posterior [noncoronary] aortic valve cusp; S.T. = septal leaflet of tricuspid valve). (Reprinted from Edwards JE, Burchell HB. The pathologic anatomy of deficiencies between the aortic root and the heart, including aortic sinus aneurysms. *Thorax* 1957;12:125-39, by permission.)

When a sinus of Valsalva aneurysm ruptures into the right atrium or right ventricle, a harsh continuous murmur is produced. As first outlined by Morch and Greenwood [10] this murmur must be differentiated from the murmurs of a patent ductus arteriosus, ventricular septal defect with associated aortic insufficiency, aortopulmonary window, coronary arteriovenous malformation, or pulmonary arteriovenous malformation. With echocardi-

ography and angiography the diagnosis is easily confirmed except in instances where a sinus of Valsalva aneurysm sac obstructs flow through a subjacent ventricular septal defect and thereby impedes visualization of the septal defect. The fact that 30% to 60% of sinus of Valsalva aneurysms are associated with ventricular septal defects emphasizes the importance of visually confirming ventricular septal integrity at the time of surgical repair.

Fig 3. This drawing illustrates the relationship of the sinuses of Valsalva to the structures of the right side of the heart. In their article, Jones and Langley demonstrated an understanding of the anatomy relevant to sinus of Valsalva aneurysms but did not develop a specific classification system. (A = aorta; I.V.S. = interventricular septum; L.C.S. = left coronary sinus; N.C.S. = noncoronary sinus; P.A. = pulmonary artery; R.A. = right atrium; R.C.S. = right coronary sinus; R.V. = right ventricle; S.V.C. = superior vena cava; T.V. = tricuspid valve.) (Reprinted from Jones AM, Langley FA. Aortic sinus aneurysms. *Br Heart J* 1949;11:325-41, by permission.)

Surgical Technique

Before the development of devices and techniques for extracorporeal support, ingenious methods were devised for the closure of ruptured sinus of Valsalva aneurysms using hypothermia and inflow occlusion [11, 12]. The method developed by Morrow and colleagues [11] employed a compressed polyvinyl plug that was passed into the aorta then guided through the mouth of the aneurysm to occlude its orifice. Bigelow's method [12] used hypothermia to 29°C and inflow occlusion to allow suture closure of the aneurysm under direct vision through a right ventriculotomy.

In the cases published by Dr Lillehei and associates, a pump-oxygenator was used to temporarily provide cardiopulmonary function. This oxygenator was a bubble-type device that had been developed and tested in laboratory animal studies by Drs Lillehei, DeWall, Read, Warden, and Varco [13]. It consisted of a vertical blood-oxygen mixing tube that emptied into a spiral settling (ie, defoaming) tube. The oxygenated and defoamed blood then passed into a reservoir from which it was pumped into the patient's arterial system (Fig 5).

In the 3 cases of Dr Lillehei, the ascending aorta was clamped during cardiopulmonary bypass and the sinus of Valsalva aneurysm was repaired (Fig 6). While the repair was accomplished in the first case, retrograde perfusion of the heart using techniques developed in the laboratory [14] maintained myocardial blood flow. Although the technique of retrograde perfusion of the heart had been previously described by other investigators [15], the studies performed by Dr Lillehei's group determined myocardial oxygen consumption and transmyocardial lactate gradients during retrograde perfusion, and critically ex-

amined blood flow distribution to the right and left ventricles. These experiments defined levels of coronary venous pressure and flow that were tolerated by the venous system and still provided adequate temporary support for myocardial metabolism. In a separate prescient study [16] normothermic continuous retroperfusion of hyperkalemic blood was proposed as a method for producing asystole and reducing myocardial oxygen consumption, although this modification of the retroperfusion technique was not used in the patients who had sinus of Valsalva repair.

The second and third patients had cardiac asystole induced by the injection of hyperkalemic blood (2.5% potassium citrate diluted in oxygenator blood) into the coronary circulation. Repair of the aneurysm was then accomplished in the arrested, nonperfused heart. The periods of cardiopulmonary bypass for these three operations were 23, 10, and 17 minutes. None of the patients in Dr Lillehei's report had associated congenital cardiac defects and none had aortic valve insufficiency.

When a ventricular septal defect is associated with a sinus of Valsalva aneurysm, repair of both fenestrations can be made with a single patch if the septal defect is subjacent to the aneurysm [17]. If the septal defect is in a location other than directly subjacent to the aneurysm, then the defects should be repaired separately. It is possible to repair a ventricular septal defect subjacent to a sinus of Valsalva aneurysm through a transaortic exposure; however, this places the specialized conduction system at higher risk for injury than closure of the ventricular septal defect through a right-sided exposure.

Aortic valve replacement with one of the usual prosthetic devices is used to treat severe aortic insufficiency associated with a sinus of Valsalva aneurysm. For less

Fig 4. (A) Gross appearance of a ruptured sinus of Valsalva aneurysm. (B) Transaortic view of a ruptured sinus of Valsalva aneurysm. The insert is a detailed view of a ruptured sinus of Valsalva aneurysm. (Reprinted from Jones AM, Langley FA. Aortic sinus aneurysms. *Br Heart J* 1949;11:325-41, by permission.)

severe aortic insufficiency repair of the aortic valve as described by Trusler and associates [18] may be used. In this operation, the aortic valve and annulus are carefully inspected, special attention being paid to the prolapsing cusp responsible for valvular incompetence. After completion of closure of the sinus of Valsalva aneurysm and associated ventricular septal defect (if present), the prolapsing valve leaflet is brought into proper alignment with the other leaflets. At this point the surgeon must judge the amount of excess leaflet tissue and decide if plication of the leaflet at the level of the commissure will restore aortic valve competency (Fig 7). The plicating sutures are reinforced with small pledgets and are taken through the wall of the aorta.

Surgical Outcome

All of the patients in Dr Lillehei's group survived operation. The duration of follow-up was not specified; however, all patients were described as doing well and as experiencing distinct improvements in health after closure of their aneurysms. The postrepair changes in systemic

blood pressure and heart size were documented by pressure tracings and chest roentgenograms.

In his closing remarks, Dr Lillehei stated that "... in this condition the aortic valves are usually normal, so that the surgery can be completely corrective" [19]. This remark was subsequently validated by the experience of other surgeons. The early mortality after repair of congenital sinus of Valsalva aneurysms ranges from 0% to 12% in reported series [3-5, 20] and is primarily related to coexisting cardiac malformations and ventricular dysfunction due to chronic aortic insufficiency. Interestingly, the incidence of severe pulmonary hypertension is low despite the association of sinus of Valsalva aneurysms and ventricular septal defects. This finding may be related to the obstruction to shunt flow posed by the aneurysm sac [20].

Longer term results of sinus of Valsalva aneurysm repair have been reported by several groups [3-5, 21-24]. Recurrence of the aneurysm is rare. In one unusual case, recurrent rupture of a sinus of Valsalva aneurysm was reported 30 years after repair with a polyvinyl plug [25]. The vast majority of patients have persistent improvements in functional class, and late morbidity is most commonly due to recurrence of a previously repaired

Fig 5. The original bubble oxygenating device developed at the University of Minnesota is illustrated. This oxygenator was made from inexpensive disposable components and was the forerunner of the single-component disposable bubble oxygenating devices. (A) In 1 patient the sinus of Valsalva aneurysm was repaired using an aortotomy and right ventriculotomy that were performed while the heart was supported with retrograde coronary sinus perfusion. (B) In 2 patients hyperkalemic cardioplegic arrest was used to provide asystole during repair of the ruptured sinus of Valsalva aneurysm. (Reprinted from Lillehei CW, Stanley P, Varco RL. Surgical treatment of ruptured aneurysms of the sinus of Valsalva. *Ann Surg* 1957;146:459-72, by permission.)

Fig 7. The aortic valve repair as described by Dr Trusler is illustrated. After the aortic valve cusps are aligned, plegeted sutures are used to reduce redundant leaflet tissue. (Reprinted from Trusler GA, Moes CAF, Kidd BSL. Repair of ventricular septal defect with aortic insufficiency. *J Thorac Cardiovasc Surg* 1973;66:394-403, by permission.)

be left untreated at the time of repair, although in the combined experience reported from the University of Alabama at Birmingham and Green Lane Hospital 4 of 17 patients with aortic insufficiency at the time of aneurysm repair eventually required reoperation. Of the patients who required operative treatment of aortic valve insufficiency at the time of aneurysm repair, 4 had Trusler repairs and 1 had repair of an avulsed commissure, whereas 10 patients had valve replacement [20].

Treatment of Unruptured Sinus of Valsalva Aneurysms

Unruptured sinus of Valsalva aneurysms are usually asymptomatic; therefore, the natural history of unruptured sinus of Valsalva aneurysms is impossible to define accurately. In the absence of secure information, the treatment of these aneurysms remains controversial. Extracardiac sinus of Valsalva aneurysms, including aneurysms of the left coronary sinus, are rare and will produce rapidly fatal tamponade upon rupturing. A recent series of 3 such patients was reported from Hospital Broussais in Paris [26]. The excellent results achieved in these patients argue strongly for the repair of unruptured extracardiac sinus of Valsalva aneurysms. The excellent results reported for a small number of unruptured asymptomatic intracardiac sinus of Valsalva aneurysms suggests that surgical treatment may be advisable in light of the potential complications referable to these aneurysms [27, 28]. However, one report of an aneurysm that was monitored without operative intervention for 19 years refutes this notion [29]. Unruptured sinus of Valsalva aneurysms that coexist with cardiac pathology requiring operation are usually corrected at the time of operation [30, 31].

Summary

Congenital sinus of Valsalva aneurysms most commonly rupture into a chamber of the right heart and produce symptoms related to left to right shunting of blood and aortic insufficiency. To solve the surgical problems posed by ruptured sinus of Valsalva aneurysms, Dr Lillehei and associates applied their clinical and experimental experiences with extracorporeal circulation, information regarding the pathology of sinus of Valsalva aneurysms, and data from studies of myocardial protection using retrograde perfusion and cardioplegic arrest. The innovative surgical techniques of extracorporeal circulation and myocardial protection that were used successfully in Dr Lillehei's 3 patients with ruptured sinus of Valsalva aneurysms were subsequently used by scores of cardiac surgeons for treating a variety of other cardiac pathology.

This work was completed during Dr Holman's tenure as an Established Investigator of the American Heart Association.

Editor's Note

We asked Dr Lillehei for a response to Dr Holman's interesting article

Dr Lillehei's Commentary

It was a pleasure to have this opportunity to read Dr Holman's concise, yet thorough review of all aspects of congenital aneurysms of the sinus of Valsalva. He has summarized very well the anatomy, pathophysiology, associated lesions, surgical techniques for repair, and results of surgical corrections of the ruptured variety.

In the historical note he describes the first successful surgical corrections, all done with cardiopulmonary bypass by our group at the University of Minnesota, using our very simple and very effective disposable bubble oxygenator (see Fig 5). All 3 patients in this initial report were successfully operated on in 1956. One of these early patients has been lost to follow-up, but the other 2, now 37 years since operation, continue to have normal, active lives without cardiac problems related to their birth defect.

It is noteworthy, as Dr Holman has pointed out, that our first patient operated on in May 1956 described the clinical use of retrograde perfusion of the coronary sinus to achieve cardioplegia and to preserve ventricular integrity. We previously had become aware of a report of the Harvard physiologist, H. R. Pratt, published in 1898 (the sixth paper in the first issue of *American Journal of Physiology*) that the myocardium could be nourished from retrograde perfusion of oxygenated blood into the thebesian and coronary veins. As Dr Holman noted, we had thoroughly studied the physiology of retrograde perfu-

sion experimentally [14, 16], confirming Pratt's observations. We then applied this method for the first time clinically in early 1956 in patients with acquired aortic valve disease undergoing open repair, the Valsalva patient noted herein, and to carry out a "modern switch operation" in a baby with complete transposition [14].

Despite our very favorable reports, and those of several others at that time, the method lay clinically dormant for some 25 years! In recent years, retrograde coronary sinus perfusion has achieved widespread recognition among cardiac surgeons and cardiologists as a very valuable method to supply oxygenated blood, cardioplegic solutions, lytic enzymes, or other substances to the ventricular myocardium.

An interesting afterthought for students of the vexing process of creativity is the fact that it sometimes takes a very good idea years to mature and be widely accepted. That observation should be an inspiration to investigators (often young) who may be confused or dismayed by a lack of prompt recognition!

Inflammatory Response to Cardiopulmonary Bypass

John Butler, FRCSI, Graeme M. Rocker, MRCP, and Stephen Westaby, FRCS

Department of Cardiothoracic Surgery, Oxford Heart Centre, John Radcliffe Hospital, Oxford, England

Cardiac operations with cardiopulmonary bypass cause a systemic inflammatory response, which can lead to organ injury and postoperative morbidity. Causative factors include surgical trauma, contact of blood with the extracorporeal circuit, and lung reperfusion injury on discontinuing bypass. Advances in immunological techniques have allowed measurement of both plasma and intracellular components of this multifaceted perioperative response. This includes activation of the complement, coagulation, fibrinolytic, and kallikrein cascades, activation of neutrophils with degranulation and protease

enzyme release, oxygen radical production, and the synthesis of various cytokines from mononuclear cells (including tumor necrosis factor, interleukin-1, and interleukin-6). Advances in our understanding of the interactions between these markers of cellular and humoral responses to cardiopulmonary bypass will enable more effective intervention to reduce the deleterious effects and improve the outlook for patients undergoing cardiac operations beyond the 1990s.

(*Ann Thorac Surg* 1993;55:552-9)

In the early 1980s the contribution of complement activation and pulmonary leukosequestration to the morbidity associated with cardiopulmonary bypass (CPB) was the subject of many reports [1, 2]. It was attractive to link the activity of a few measurable markers of humoral and cellular activation to postoperative pulmonary dysfunction. In 1993 we can determine many more markers of the complex and sometimes detrimental consequence of blood contact with artificial surfaces; in addition an "acute phase response" to surgical trauma is increasingly recognized. The purpose of this review is to discuss some of the components of the systemic inflammatory response to CPB and consider how they might relate to the morbidity associated with modern cardiothoracic surgery.

Systemic Inflammatory Response to Extracorporeal Circulation

After exposure of blood to artificial surfaces inflammatory responses are activated including the complement, coagulation, fibrinolytic, and kallikrein cascades. Leukocyte activation occurs and platelet function is impaired. These humoral and cellular systemic responses are manifest in cardiac surgical practice as the "postperfusion" or "post-pump" syndrome with leukocytosis, increased capillary permeability, accumulation of interstitial fluid, and organ dysfunction [1, 2]. Aspects of these responses, their interactions and the implications for lung injury are considered below.

Complement

Complement activation during CPB [1-5] leads to the formation of anaphylatoxins C3a and C5a mainly via the alternative pathway [6]. Activation of the classic pathway (recognized by C4a formation) also occurs at blood/air

interfaces [1] and through the formation of heparin-protamine complexes [7]. Less substantial generation of C3a can be induced by plasmin [8] and kallikrein [9]. The enzyme carboxypeptidase B removes the arginyl residue to form C3a/C5a desArg [6], rapidly reducing C3a activity while C5a desArg continues to have active properties. Operation itself may activate complement [10], but levels of C3a rise dramatically only with commencement of CPB and peak at the end of CPB. Levels of C3a are related to the duration of CPB [2] and return to pre-CPB values after 48 hours. Cardiac and pulmonary dysfunction, renal failure, and bleeding tendencies have been related to C3a levels 3 hours after CPB [2].

Complement activation alone may be insufficient to induce acute lung injury [11], but small amounts of C5a can induce neutrophil aggregation and margination, and the binding of C5a to specific neutrophil membrane receptors [12, 13] (limiting its detection in plasma during CPB) stimulates neutrophil adherence to vascular endothelium [14], potentially important at the time of lung reperfusion. The complement fractions C3b and inactivated C3b, bound to the materials of the extracorporeal circuit, may induce neutrophil degranulation and monocyte release of interleukin-1 β [15]. Additional terminal complement cleavage products (C5b-9) generated during CPB [16] could augment neutrophil activation by stimulation of intracellular arachidonite metabolism [17]. In models of complement activation, leukopenia, increases in pulmonary artery pressure, and impaired oxygenation are accompanied by histologic evidence of sequestration of leukocytes in the capillary bed and endothelial cell damage [18]. Complement-induced capillary injury similarly occurs in models of the adult respiratory distress syndrome [19]. There is no clear consensus on the effects of different types of oxygenator used during CPB on complement activation [20-23].

Coagulation and Fibrinolysis

Negatively charged surfaces of the CPB circuit and exposed collagen from tissue injury activate factor XII [24]. Factor XIIa can stimulate neutrophil aggregation and exocytosis of elastase [25]. It can generate kallikrein, which induces neutrophil chemotaxis [26], aggregation [27], and degranulation [28]. Kallikrein activates factor XII by positive feedback and induces release of bradykinin, which may cause vasodilation and increased vascular permeability [29]. Fibrinolysis is enhanced during CPB [30], and fibrin-fibrinogen degradation products generated may impair fibrin formation [31] and platelet function [32], and disrupt the endothelial monolayer [33]. In combination these effects might lead to capillary injury, extravascular fluid transudation, and disturbance of normal hemostasis.

Leukocytes

An immediate fall in leukocyte numbers with loss of mature granulocytes and macronuclear cells occurs at the onset of CPB, due to hemodilution or adhesion of neutrophils to the absorbed protein layer in the extracorporeal circuit [34]. Leukopenia is more marked with bubble oxygenation [35]. A later leukocytosis occurs due to mobilization of marginated cells and release of immature neutrophils from bone marrow. This response is abrogated during hypothermia [36].

Neutrophils and lymphocytes remain in the lungs as pulmonary blood flow falls on starting CPB. This early leukosequestration may be a physical property as intrapulmonary neutrophil counts are inversely related to total pulmonary blood flow [37]. As pulmonary blood flow is restored after aortic cross-clamp removal, neutrophils, but not lymphocytes [36], are selectively trapped in the lung capillaries. There is a positive correlation between extent of pulmonary vascular leukosequestration, the length of aortic cross-clamp time, and the total duration of CPB [1]. Bubble oxygenation may initiate significantly more leukocyte sequestration than silicon membrane oxygenation [21]. Sequestration may be a transient phenomenon and is rarely detected with full pulmonary blood flow on discontinuation of bypass [38, 39]. Sequestered neutrophils could be inactive and innocuous [40, 41], but there is evidence that release of lipid peroxidation products (reflecting cell membrane injury) occurs at the same time as pulmonary neutrophil sequestration after removal of the aortic cross-clamp [42].

Primary (azurophil) neutrophil granules containing neutral serine proteases such as elastase, and secondary granules containing several unique glycoproteins including lactoferrin, have important roles in inflammation and host defense that may be relevant in the response to CPB.

Plasma lactoferrin levels peak before CPB [43], and the role of lactoferrin remains uncertain, with potential positive or negative effects on production of oxygen-derived free radicals [44, 45]. A significant role for lactoferrin in the transfer of iron from transferrin into tissue ferritin has been suggested [46], and plasma iron levels are reduced as part of the acute phase response [47].

Neutrophil elastase is of potentially greater importance

due to a high intracellular concentration and low substrate specificity. It is a potent enzyme, and changes in coagulation proteases [48], inactivation of their principal antagonists [49], platelet Gp-Ib hydrolysis [50], and exposure of fibrinogen receptors on the platelet surface [51] are some of its effects that may be relevant to the hemorrhagic complications of prolonged CPB. Elastase has been implicated in neutrophil-mediated endothelial injury in vitro [52] and can initiate the breakdown of the body's own vital tissues if released extracellularly [49].

Elastase release from neutrophils has been reported during CPB [43, 53-55]. An association between pulmonary leukosequestration and increased pulmonary permeability has been reported in dogs after CPB [56], and the capacity for elastase-related lung parenchymal and endothelial injury suggests a potential role for this serine protease in the capillary, pulmonary, and compartmental fluid changes associated with CPB.

Elastase and Antiproteases

To protect against elastase-induced injury, tissues in vivo are bathed in antiproteases. α_1 -Antiprotease, irreversibly inhibiting neutrophil elastase by forming an enzyme-inhibitor complex, plays the major role in elastase regulation because of its high molar concentration in plasma and the rapid inactivation of its major target enzyme [49]. The half-life of elastase- α_1 -antiprotease complex in plasma is about 1 hour [57].

Increased plasma levels of elastase- α_1 -antiprotease complex may be caused by operative trauma [58]. During CPB plasma elastase complex levels rise progressively and peak at the end of the operation [55]. The rise on lung reperfusion may represent washout of activated neutrophils from the pulmonary circulation. Levels are unrelated to peripheral neutrophil counts but do relate to the duration of bypass [54, 59], suggesting neutrophil degranulation or injury during the period of extracorporeal circulation. Despite peripheral neutrophil activation it is probable that intrapulmonary tissue injury is more closely related to intraalveolar elastase release [60, 61].

Oxygen Free Radicals

The defenses against extracellular elastase release may be impaired by oxygen-derived free radicals released during CPB. Free radicals may be neutrophil-derived [62] or produced by xanthine oxidase catalysis of the oxidation of hypoxanthine in reperfused tissues [63]. Subsequent oxidation of the methionine reactive site of α_1 -antiprotease markedly slows the rate of inhibition of elastase and reduces the stability of elastase-inhibitor complexes.

Neutrophils can generate oxygen radicals during CPB by membrane- and granule-related mechanisms. Membrane-bound NADPH oxidase enzyme complex can generate the oxygen metabolites superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical ($OH^\cdot$) [64]. Primary granule-derived myeloperoxidase catalyzes the oxidation of chloride ion in the presence of hydrogen peroxide to yield hypochlorous acid (HOCl) [65], which has been implicated as a cytolytic mediator. Evidence supporting free radical generation during cardiac opera-

tions is provided by increased plasma lipid peroxidation products after aortic cross-clamp removal [42] and elevated hydrogen peroxide levels at the end of CPB [66]. Peroxidation products may cause direct injury to lipids and nucleic acids, and by denaturing cell surface proteins further augment tissue injury [67].

Endotoxin and Cytokines

Recent interest in acute lung injury has focused on the role of endotoxin and the systemic inflammatory cytokines. Cytokines are endogenous polypeptides produced by a variety of cell types. They serve for signal communication between cells involved in immunity and inflammation and are thought to play an essential role in the pathogenesis of shock and multiple organ failure during sepsis. Monocytes "primed" by sepsis or surgical procedures such as CPB may release systemic inflammatory cytokines including tumor necrosis factor- α (TNF), interleukin-1 β (IL-1), and interleukin-6 (IL-6).

Endotoxins are lipopolysaccharides derived from the walls of degraded gram-negative bacteria. Their biologic effects include activation of the coagulation cascade, complement by both the classic and alternative pathways, the oxidative burst response in neutrophils, and increased adhesiveness of vascular endothelial cells [68, 69]. In vitro, endotoxin induces endothelial cell injury by an elastase-dependent mechanism [52]. In animal models low-dose endotoxin causes transient pulmonary neutrophil accumulation with lung injury if systemic neutrophil activation also occurs [70].

During CPB splanchnic vasoconstriction could lead to intestinal mucosal injury, allowing leakage of endotoxin into the bloodstream while clearance may be impaired after CPB due to suppression of the reticuloendothelial system [71]. In one study, plasma endotoxin was maximal at 90 minutes of perfusion, decreasing significantly 6 hours after CPB and gradually falling until the seventh postoperative day [72]. Another study found gradually rising endotoxin levels during CPB, peaking at the time of aortic cross-clamp removal and falling to baseline levels 45 to 75 minutes after CPB [73]. Endotoxemia during CPB has been related to enhanced generation of free radicals by neutrophils, but there is no obvious relation to postoperative morbidity [74, 75].

In the absence of a rise in plasma TNF a significant endotoxin contribution to postoperative morbidity would be unlikely. Using the limulus amoebocyte lysate assay for endotoxin [76], positive assays have been obtained in "sterile" infusion solutions and concentrated commercial heparin preparations [75] perhaps due to cross-reacting pyrogens for which there are many sources in cardiac operations, including components of the extracorporeal circuit, infusion solutions, and surgical instruments.

Tumor necrosis factor- α is produced by activated monocytes, lymphocytes and Kupffer cells. Known previously as cachectin, it is distinguished from TNF- β (lymphotoxin), a structurally related polypeptide. Factors triggering TNF synthesis include C5a [77], interleukin-1 β [78], gram-negative endotoxin [78], and gram-positive bacterial products [79]. Induction of an acute phase response by

TNF has been demonstrated in vitro, with increased synthesis of hepatic proteins and glycoproteins [80]. It has been implicated in septic lung injury both in animals [81] and in humans [82]. Effects on neutrophils include production of an oxidative burst, degranulation, increased phagocytic activity, and increased expression of leukocyte adhesion molecules [83, 84].

To date reports on the plasma TNF response to CPB have been conflicting. A significant increase in TNF, preventable by dexamethasone administration, has been observed after removal of the aortic cross-clamp [85]. No plasma TNF was detected in another study [86], and although others found detectable plasma TNF in 10 of 19 patients preoperatively there was no significant change during or after CPB [55].

Interleukin-1 β is an important component of inflammatory and immune responses. Factors inducing IL-1 production include complement anaphylatoxins [87] and endotoxin [88]. Adherence to foreign surfaces activates monocyte production of IL-1 [89]. Fever, neutrophilia, and enhanced release of C-reactive protein are mediated by IL-1 [90]. Cultured endothelial cells stimulated with TNF or IL-1 become hyperadhesive for neutrophils [91]. Interleukin-1 β induces release of specific granule contents from human neutrophils [92] and induces synthesis of IL-6 by monocytes [93].

Increased production of IL-1 has been transiently found after CPB, maximal at 24 hours, coinciding with a peak in body temperature [86]. In this study IL-1 production was assessed by measuring functional activity and IL-1 antigen concentration in cell lysates from monocytes of patients during and after CPB. By contrast plasma IL-1 was not detected in two other reports [39, 59], perhaps reflecting a more important role as a paracrine mediator [94]. In general, IL-1 is not detectable systemically during most forms of acute inflammation [95-98].

Interleukin-6 is involved in the modulation of the acute phase response [99]. It is produced by a variety of activated cell types including monocytes [100], lymphocytes [101], and endothelial cells [102]. It induces acute phase proteins in vivo [99] and stimulates the full spectrum of acute phase proteins in adult human hepatocytes in vitro [103]. Interleukin-6 can induce fever [104] and elicit the release of adrenocorticotrophic hormone [105]. It has been detected in serum after burn injury [104], after elective operation [106], and in septic patients [95, 107]. After general operation the serum IL-6 level rises within 2 to 4 hours of surgical incision, and the response correlates with the duration of the operation. Peak levels occur 4 to 6 hours postoperatively [108]. Interleukin-6 may be a sensitive early marker of tissue damage, and levels may be of prognostic value in septic shock [105]. The postoperative rise in IL-6 level may be a protective mechanism as IL-6 inhibits endotoxin-induced TNF production by monocytes [109].

In response to CPB similar rises in plasma IL-6 levels occurred with both membrane and bubble oxygenation [39]. Plasma C-reactive protein (a hepatic acute phase protein) reaches a later peak [55]. After bypass fever, leukocytosis, a negative nitrogen balance, increased vas-

cular permeability, and an increase in the synthesis of hepatic acute phase proteins are all compatible with IL-6 release, and the pattern of the IL-6 response (a 4-hour postoperative peak and sustained elevation at 48 hours [39]) is consistent with a role as a major mediator of the acute phase response to CPB.

Unresolved issues in the measurement of circulating cytokines include effects of binding to plasma proteins, assay inhibition by specific plasma proteins, rapid degradation by plasma proteases, rapid clearance from the circulation by cell receptors, and transiently elevated levels that are easily missed [88]. Interpretation of circulating IL-1 levels is further complicated by the presence of specific plasma inhibitors that act as IL-1 receptor antagonists on target cells [110-112]. Production of IL-1 inhibitor increases as monocytes mature into macrophages [113]. Soluble specific protein inhibitors, possibly shed receptors, have been described for IL-1 [114] and TNF [115]. No IL-6 inhibitor is currently known, but IL-6 does bind to the carrier protein α_2 -macroglobulin.

Intraalveolar Events

Systemic markers of inflammatory responses may not adequately reflect intrapulmonary events after CPB. Determination of intraalveolar free elastase or elastase complex might be better indicators of elastase-related lung injury, but in one study no elastase activity was detected 4 hours after CPB [116]. Timing of the lavage is obviously critical. Intraalveolar TNF and IL-1 have been demonstrated in patients with the adult respiratory distress syndrome [117, 118], but intraalveolar levels of these cytokines have yet to be investigated after CPB.

Therapeutic Intervention

If systemic inflammatory mediators contribute to the morbidity of extracorporeal perfusion, limitation of the intensity of the response should be possible with treatment including corticosteroids, oxygen radical scavengers, neutrophil granule stabilizers, and specific monoclonal antibodies.

Pretreatment with corticosteroids has been claimed to minimize lysosomal enzyme release during CPB, and complement-induced neutrophil aggregation [119] is inhibited *ex vivo* [120]. Both corticosteroids [121] and aprotinin [122] reduce plasma levels of neutrophil elastase after aortic cross-clamp removal, and dexamethasone administration prevents TNF production during CPB [85]. Corticosteroids are not used routinely as prophylaxis during CPB; there is no evidence of effective *in vivo* complement activation inhibition, cellular host defense mechanisms are impaired, and higher endotoxin levels have been reported in treated patients [123].

Reduction of lung injury may be achieved by inhibiting neutrophil activation. Neutrophil depletion by filtration protects against CPB-induced lung injury in animal models [120]. Calcium channel blockers may inhibit neutrophil metabolic pathways involved in the production of injurious substances. The continuous infusion of nifedipine during CPB causes significantly lower levels of elastase-

α_1 -antiprotease complex and lactoferrin but not C3a [53]. In animal studies, the combination of superoxide dismutase and catalase protects host tissues from oxidative damage by activated neutrophils [124]. The antioxidants mannitol and allopurinol reduce hydrogen peroxidase production during clinical CPB [125]. Nonenzymatic free radical scavengers that could be of benefit include vitamins C and E [126]. The iron-chelating agent deferoxamine, binding free iron and thereby interfering with free radical generation, decreases acute lung injury after complement activation [127] and inhibits lipid peroxidation during CPB [128].

Aprotinin (as a nonspecific enzyme-inhibitor) was originally administered during CPB in hope of abrogating the inflammatory response to CPB. A marked reduction in postoperative bleeding was noted [122, 129-131]. Improved hemostasis may have been achieved by inhibition of the plasmin degradation of the platelet membrane glycoprotein Gp-Ib [132]. Although routine use of aprotinin during cardiac operations has been recommended [131], its effect on coronary graft patency has yet to be determined.

If cytokine responses to CPB are important there are several potential therapeutic possibilities. Neutrophils that have been activated with inflammatory cytokines and incubated with the methylxanthine pentoxifylline show decreased superoxide production, decreased degranulation, decreased adherence, and increased chemotaxis [133]. Pentoxifylline inhibits the inflammatory action of IL-1 and TNF on neutrophil function [133]. Models simulating adult respiratory distress syndrome demonstrate a diminution of lung injury if pretreated with pentoxifylline [134-136]. Infusion in human volunteers abolishes the endotoxin-induced rise in TNF (but not IL-6) [137], and pulmonary and cardiac damage are diminished in a model of CPB [138]. However, in a clinical study of CPB, a postinduction infusion of pentoxifylline ($1 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) did not significantly reduce plasma levels of elastase complex, IL-1, or IL-6 or improve postoperative oxygenation [59].

Monoclonal antibodies against TNF and IL-1 receptors prevent endotoxin-induced shock in animal models of sepsis [81, 139]. Monoclonal antibodies to endotoxin reduce mortality in gram-negative bacteremia and septic shock in humans [140] and given prophylactically reduce septic shock and mortality in surgical patients at high risk of gram-negative infection [141]. Therapeutic intervention to reduce cytokine-related responses may, however, result in inhibition of T-cell proliferation, B-cell proliferation, and lymphokine generation, thus diminishing host defense and making the patient more vulnerable to severe infection, and there seems no justification for use of monoclonal antibodies to endotoxin in CPB at present.

Conclusion

The whole body inflammatory response to CPB is considerably more complex than it seemed a decade ago. The acute phase response to trauma, in which cytokines are intimately involved, may be an integral part of this

process. Ten years hence, our expanding knowledge of inflammatory mediators may allow a better understanding of CPB-related morbidity, significant improvements in the biocompatibility of perfusion circuits with diminished injurious systemic responses, less lung injury, and an improved outlook for CPB beyond the 1990s.

1992 Meeting

Southern Thoracic Surgical Association

The Thirty-ninth Annual Meeting of the Southern Thoracic Surgical Association was held at the Saddlebrook Golf and Tennis Resort, Wesley Chapel, Florida, November 5-7, 1992. The President was William A. Cook, MD.

Officers elected for the coming year are: *President*, Gordon F. Murray, MD; *President-Elect*, Ronald C. Elkins, MD; and *Vice President*, Kit Arom, MD.

The following applicants were elected to membership:

Erle H. Austin III, MD
Louisville, KY

George William Johnson, Jr, MD
Houston, TX

Pamela S. Peigh, MD
St. Louis, MO

John C. Austin, MD
Nashville, TN

Roy L. Kingry, Jr, MD
Tyler, TX

Samuel B. Pollock, Jr, MD
Louisville, KY

Frank P. Catinella, MD
Fort Lauderdale, FL

John Thomas Kirchmer, Jr, MD
Beaumont, TX

John D. Randolph, MD
Oklahoma City, OK

Daniel Michael Cohen, MD
Greenville, NC

A. Michael Koury, MD
Jackson, MS

Michael Rosenbloom, MD
St. Louis, MO

Joel D. Cooper, MD
St. Louis, MO

Stephen L. LaMendola, MD
Beaumont, TX

William H. Ryan, MD
Dallas, TX

Edward Frank Crocker, Jr, MD
Lake Charles, LA

Michael Mack, MD
Dallas, TX

Cary L. Stowe, MD
Orlando, FL

Thomas M. Egan, MD
Chapel Hill, NC

Michael R. Mill, MD
Chapel Hill, NC

Stephen L. Wallenhaupt, MD
Winston-Salem, NC

Peter Einstein, MD, PhD
Memphis, TN

Michael Christopher Murphy, MD
St. Louis, MO

Thomas H. Wareing, MD
St. Louis, MO

Elevated to senior membership were: Orville W. Clayton, MD, Roy H. Crispin, MD, J. Ralph Dunn, Jr, MD, William H. Edwards, MD, R. C. Garby, MD, Loyde H. Hudson, MD, Edward W. Jenkins, MD, Charles R. Kessler, MD, Nelson H. Kraeft, MD, Donald E. McDowell, MD, Judson Randolph, MD, Orval E. Riggs, MD, Hasmukh H. Shah, MD, E. Wilson Staub, MD, and Robert J. Wilder, MD.

The President's Award for the best scientific paper given at the 1991 meeting was presented to Ross M. Ungerleider, MD, William Greeley, MD, Ronald Kanter, MD, and Joseph Kisslo, MD, for their paper "The 'Learning Curve' for Surgeons for Evaluating Repair of Congenital Heart Defects Using Intraoperative Echo."

The 1993 meeting will be held at Marriott's Bay Point Resort, Panama City Beach, Florida, November 4-6, 1993. Chairman of the Program Committee will be Harvey I. Pass, MD, Chairman of the Postgraduate Committee will be Constantine Mavroudis, MD, and Chairman of the Membership Committee will be Marion R. Lawler, Jr, MD.

Hendrick B. Barner, MD
Secretary-Treasurer
Southern Thoracic Surgical Association
401 N Michigan Ave

Carotid Endarterectomy During Aortic Clamping*To the Editor:*

Weiss and co-workers [1] recently described a technique for combining carotid endarterectomy with a cardiac operation in which cardiopulmonary bypass was used to achieve systemic hypothermia (20°C) for cerebral protection. Both the carotid endarterectomy and the cardiac procedure were carried out during a single period of aortic cross-clamping, and a continuous retrograde infusion of blood was used for myocardial protection. In their report, Weiss and co-workers stressed the advantages of hypothermic cerebral protection during the period of carotid clamping, including elimination of the need for a carotid shunt.

Weiss and co-workers are to be commended for their excellent results (no strokes, 1 death, in 23 patients) with this innovative approach, but certain aspects of their technique merit review and comment. They exposed the carotid artery first and then proceeded with cardiopulmonary bypass, aortic clamping, and continuous retrograde cardioplegia (first warm, then cold). While the patient was being cooled, the early stages of the cardiac procedure were carried out. When a bladder temperature of 20°C was reached, the cardiac procedure was interrupted and the carotid endarterectomy was performed.

They point out that their technique is novel because in previous reports of carotid endarterectomy on bypass, the endarterectomy was performed before aortic cross-clamping while the heart was beating or ejecting. In those other reports, systemic temperatures were lowered only to 28°C to 30°C "lest the heart fibrillate." Weiss and co-workers note that by lowering the systemic temperature further to 20°C they provided an additional decrease in cerebral oxygen requirements and thus enhanced cerebral protection.

We strongly endorse their concept of combined operations with hypothermic cardiopulmonary bypass, and have also used systemic hypothermia in the range of 20°C in 15 patients over the past 2 years. Our approach has been different, however, and we believe far simpler, because we do not clamp the aorta before the carotid endarterectomy as we are unconcerned about hypothermic ventricular fibrillation. The safety of ventricular fibrillation (even at moderate hypothermia of 30°C, not to mention at profound hypothermia of 20°C) has been amply demonstrated in numerous reports of clinical and experimental studies that we have discussed elsewhere [2].

In patients undergoing combined carotid endarterectomy and a cardiac operation, we institute routine cardiopulmonary bypass and vent the left ventricle in the manner we recently reported [3]. While the patient is being cooled to a core temperature of 20° to 22°C, the neck incision is made and the carotid artery is exposed. During this cooling interval, arterial and venous conduits are also harvested and prepared. The endarterectomy is then carried out, although the neck incision is not fully closed until later, after protamine is given. The patient is then rewarmed to 30°C while the cardiac procedure is being performed. If the cardiac procedure is an isolated coronary bypass we generally avoid cardioplegic arrest, although others might prefer to use it in these circumstances, but we do use cardioplegia for valve procedures, usually with a myocardial protection jacket, which—in these combined procedures with prolonged rewarming—is particularly protective against rewarming of the ischemic heart. Aortic cross-clamping is thus limited to the interval necessary for the cardiac procedure, and any unexpected developments that prolong the noncardiac portions of the combined procedure do not prolong aortic cross-clamping.

Although Weiss and co-workers may believe that their tech-

nique of continuous retrograde cardioplegia at 100 mL/min during aortic cross-clamping is sufficient protection, they have reported that 16 of 100 consecutive patients who underwent unspecified cardiac procedures with this technique required inotropic support for more than 24 hours [4]. That requirement suggests that it would be wise to avoid unnecessary aortic cross-clamping, because ischemic myocardial injury does occur even with low-flow continuous cardioplegia, in contrast to the experience with hypothermic ventricular fibrillation at high flow and perfusion pressures [2, 5]. We therefore suggest that consideration be given to our simpler sequential approach to combined procedures, in which carotid endarterectomy is performed on bypass before the aorta is cross-clamped. Whether cardioplegia is later used for the cardiac procedure is a separate matter of the surgeon's preference, but an unfounded reluctance to let the heart fibrillate (even at 20°C) need not dictate the conduct of the entire combined operation.

*Reply**To the Editor:*

My colleagues and I are delighted that Dr Bonchek's group has been applying this technique in their practice. Although our management of the myocardium differs, the central principle of combining the carotid and cardiac procedures to allow the use of systemic hypothermia to protect the brain during carotid endarterectomy is the same. It is our hope that as more data and technical refinements begin to surface from other institutions, we will all be able to decide if this principle should be adopted into our standard of practice of cardiac surgery.

Prosthetic Mitral Valve Replacement*To the Editor:*

A recent valve comparison article [1] described a theoretically ideal study design, has valid findings of "not significant" for all

Table 1. Thromboembolism Rates

Variable	SJ	MH
No. of thromboemboli	2	5
Follow-up (patient-years) ^a	121	105
Linearized rate (%/year)	1.65	4.76
95% confidence interval	0.3-5.1	1.7-10.2

^a The patient-years for the two valves in the above table are reversed from those given in the text, which seem to be backwards.

MH = Medtronic-Hall; SJ = St. Jude Medical.

complications, but then concludes that "there is no difference . . . with regard to early clinical results" and that "neither valve can claim superior performance or safety."

All that can be claimed is that the study failed to statistically discover a difference, not that none exists. For a large study, this is sufficient, because a difference of major importance is likely to be discovered. But in a small study, large actual differences may escape statistical detection [2].

This problem can be appreciated by considering confidence intervals for the thromboembolism rates (Table 1). Such a small study can estimate the complication rates for each valve with only very low precision; the confidence interval for each valve spans the spectrum from excellent to poor. Correspondingly, there is a very small chance of finding even a large, real clinical difference to be statistically significant. The confidence intervals overlap tremendously, and the point estimates, although quite different clinically (one is triple the other), are not statistically significant ($p = 0.181$). The fact that clinically significant differences are not statistically so is an alert that the study size may be insufficient.

A study twice as large, with the same rates, would still not quite find significance ($p = 0.059$) but one three times as large would ($p = 0.021$). If this were the case, and it could conceivably happen in this or another study, then one valve could indeed "claim superior performance."

This study is praiseworthy for its design and execution: two current widely used valves and a randomized protocol that allows valid hypothesis tests to be made. But it needs a longer follow-up, more centers, or both. It (so far) can contribute to the above conclusion, but alone cannot support it.

Reply

To the Editor:

My colleagues and I are grateful to Dr Grunkemeier for pointing out that at the present time our study failed to discover statistical significance between the performance of the Medtronic-Hall and St. Jude prostheses. We agree that a difference may exist between

these two valves, but only with longer follow-up and a larger population size can any definite conclusions be reached.

We are continuing our randomized trial, which was begun in 1986, and at the present time have introduced a second medical center in order that the population size can be expanded. In time, we hope to establish definite conclusions about the performance of these widely used prostheses.

Thoracoscopic Thymoma Resection

To the Editor:

We read with interest Landreneau and associates' [1] report of thoracoscopic resection of an anterior mediastinal tumor. Their contribution to the developing field of thoracoscopic surgery has already been significant. This is another example of how innovation is requiring us to rethink our approaches to the management of thoracic diseases. It is important for us to continually reexamine both our objectives and our outcomes in the management of our patients, lest we fall into the trap of reduplicating our past successes and failures. Doctor Landreneau and his colleagues in Pittsburgh are to be commended for their efforts in presenting this case report for our consideration.

Because Dr Landreneau's recommendation is both new and controversial, Dr Pairolero's invited commentary is also worthy of consideration. We would agree with Dr Pairolero that long-term survival must not be compromised in the name of less morbid surgery. We take exception, however, to his implication that video thoracic surgical resection is, by nature, limited and diagnostic rather than therapeutic. The resurgence of thoracoscopic surgery is still in its infancy and, because of this, most of

Fig 1. Total thymus specimen containing stage 1 thymoma removed thoracoscopically. The needle points to the thymoma.

Fig 2. The cut surface of the thymoma shown in Figure 1.

the procedures have been performed for limited indications. We do not think that this is necessarily due to the inherent limited nature of video thoracic surgery, but rather to its stage of development. We see more extensive procedures being performed as more experience is gained.

Regarding thymoma, we think that some of the controversy generated in this article and accompanying commentary could be avoided by total thoracoscopic thymectomy. As shown in Figures 1 and 2, total thymectomy can be accomplished by a thoracoscopic approach. Wider experience is obviously necessary before meaningful comparison with open approaches can be made. We do not believe that any procedure should be compromised or limited *solely* to accomplish it less invasively. If the surgeon believes that the procedure is being compromised by the thoracoscopic approach, conversion to an open, standard procedure should be performed. We believe Dr Landreneau's report continues to advance thoracoscopy into the realm of therapy and anticipate further reports. We would like to congratulate both Dr Landreneau and associates and Dr Pairolero for the stimulating presentation and discussion.

Reply

To the Editor:

Doctor Acuff and associates, along with Dr Landreneau, are strong advocates of video-assisted thoracic surgery. As Dr Acuff states in his letter, a role for thoracoscopy exists in the management of thoracic disease. The full extent of this role, however, has not yet been determined.

When compared with surgery performed through a thoracotomy, video-assisted surgery is by its very nature limited. Our

eyes and hands are immensely better at determining the gross extent of disease than any videocamera or percutaneous tool. The price, however, is an open procedure with its associated pain, short-term disability, loss of income, and reluctant patient acceptance; thus, the enthusiasm for thoracoscopy.

There is no question that some patients with benign disease, such as those with an indeterminate pulmonary nodule that proves to be a granuloma or hamartoma, are benefited by video-assisted thoracic surgery. But can the same be said for patients with malignant disease, especially those with primary lung cancer? At present this question remains unanswered. Thoracotomy with resection for malignant disease has had a known long-term track record and must be the gold standard against which other therapeutic modalities are measured. In contrast, *no* track record currently exists for thoracoscopic cancer resection other than the enthusiasm of both patient and surgeon.

We all agree that the boundaries of video-assisted thoracic surgery should be expanded; however, they must be pushed back by well-controlled scientific studies rather than by zealous enthusiasm. Thus far, nearly all reports have dealt only with the ability to perform the procedure. Most investigators, including Drs Landreneau and Acuff, do not address the question of how to manage malignancy discovered at thoracoscopy. Instead, they convey the impression that local thoracoscopic excision translates into adequate cancer treatment, a position that is not supported in fact. Until follow-up data become available, this new therapeutic modality should be approached with cautious optimism, for clearly it has *not* withstood the test of time.

Resection of Mycotic Lung Sequestra After Invasive Aspergillosis

To the Editor:

We would like to add a case report of our own and some comments to the superb experience recently published by Young and associates [1].

A 38-year-old female patient was seen in May 1991 with an acute lymphocytic leukemia. The remission obtained with induction chemotherapy was hematologically but not cytogenetically complete. Hence, a bone marrow transfer was indicated. During the neutropenic state, invasive pulmonary aspergillosis occurred. Initially, several bilateral nodules developed, and two left upper lobe lesions were rapidly cavitating. The patient was treated with intravenous liposomal amphotericin at $3 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ for 56 days (total dose of 7,435 mg); all but the two left upper lobe lesions apparently healed. Operation was considered because of a concern of relapsing aspergillosis from this reservoir during aplasia. The two cavities measured 2 and 3 cm on chest views, and there were no signs of pleural sequelae. The patient was operated on through a muscle-sparing posterolateral thoracotomy. No pleural adhesions were observed. Both lesions were easily identified on palpation and excised with stapled wedge resections using a GIA device to avoid intrapleural seeding. Both cavities contained necrotic tissues mixed up with *Aspergillus* filaments. Postoperative recovery was uneventful, and the patient underwent subsequently successful genoidentical bone-marrow transplantation 6 weeks later; no infectious complications were noted.

Traditionally, operation has been limited to the pulmonary aspergilloma developed in sequelary lesions, either because of troublesome symptoms or prophylactically [2]. Resection of mycotic lung sequestra is a recent issue [3]. As do Young and associates, we affirm that operation has a definite place in the management of cavitary disease after invasive aspergillosis. The rationale of operation is prevention of both hemoptysis and elapsing aspergillosis during subsequent marrow-depressing treatments. This attitude is encouraged by a low operative risk: these mainly young patients have few pleural adhesions (source of bleeding), and elasticity of the lung and mediastinum is normal, prone to correct pulmonary expansion after resection [2].

However, we cannot entirely subscribe to the pathogenesis advanced for hemoptysis associated with invasive aspergillosis. Young and associates hypothesize that bleeding was due to erosion of parietal vessels, as opposed to classic aspergilloma, where the bleeding would originate from the bronchial vessels. We do believe that the principal source of bleeding in invasive aspergillosis is disruption of either bronchial or pulmonary vessels. Erosion of parietal vessels is a most common phenomenon in pulmonary aspergillomas. The chronic cavities are surrounded by a huge vascular network developed as well during the initial disease (mostly tuberculosis) as by the presence of the mycetoma. The large variety of parietal pedicles feeding into this mycetoma-like vascular sponge explains the failure of preoperative embolization to prevent intraoperative bleeding [2, 4].

Again, we would like to compliment their most interesting and important publication.

Reply

To the Editor:

We thank Massard and colleagues for their comments and note their success in resection of a case of cavitating invasive aspergillosis [1]. Their case confirms the key importance of the development of cavitation in the natural history of invasive pulmonary aspergillosis. Those lesions in which cavitation had not developed resolved with intravenous amphotericin. As in our experience [2], they identified cavitation as the step that indicates reversibility of the process and as the portent of hemoptysis.

The origin of bleeding in classic aspergillomas has not been fully resolved, and we did not wish to suggest that it was

exclusively of bronchial origin. However, most authors would agree that the principal origin of major hemoptysis is the bronchial circulation [3, 4], although there may be extensive collaterals [5]. Bleeding from classic aspergillomas may on occasion arise from vascular inflammatory pedicles extending from the chest wall to the wall of the cavity [6]. We suggest, however, that direct erosion of intercostal arteries is much more likely in cavitating invasive aspergillosis. The pulmonary infarct, which gives rise to the cavity, extends to the chest wall and, in many cases, the chest wall forms one wall of the cavity. The intercostal artery thus commonly lies exposed in the wall of the cavity, an unusual occurrence in classic aspergilloma. However, as with classic aspergilloma, bleeding may have more than one origin, and successful embolization of bronchial arteries in a case of cavitating invasive aspergillosis has been reported [7].

We thank Massard and colleagues for their constructive comments and look forward to the publication of their article on pleuropulmonary aspergillosis.

Thoracic Aortic Dissection and Atherosclerotic Abdominal Aortic Aneurysm

To the Editor:

I read with interest the article by Roberts and Roberts entitled "Combined thoracic aortic dissection and abdominal aortic fusiform aneurysm" [1]. My colleagues and I have operated on an additional case of this uncommon association of abdominal atherosclerotic aortic aneurysm (AAA) and thoracic aortic dissection.

A 63-year-old man was transferred from another hospital for surgical therapy of a ruptured AAA. He had a history of systemic hypertension, gastroduodenal ulcer, right nephrectomy, and chronic renal insufficiency and had been in a program of hemodialysis since May 1988. He also had previously been diagnosed as having a silent infrarenal AAA 5 cm in transverse diameter

A

B

Fig 1. (A) Computed tomographic scan of the descending thoracic aorta with a flap typical of dissection. (B) Computed tomographic scan of the abdomen showing an atherosclerotic abdominal aortic aneurysm with calcification of the arterial wall and with dissection of the anterior aspect of the aneurysm.

(ultrasound examination). The patient experienced acute abdominal pain and hypotension. A thoracoabdominal scan showed dissection of the descending thoracic aorta and infrarenal AAA with a perianeurysmal liquid collection (Fig 1).

On February 2, 1989, the patient underwent operation on an emergency basis, and a median laparotomy was performed. A leaking infrarenal AAA 8 cm in transverse diameter was found. The infrarenal aorta and iliac arteries were clamped, and a straight 22-mm vascular graft was interposed. At the level of the proximal anastomosis the abdominal aorta was clearly dissected with a wide separation between the arterial walls. The true lumen was localized, the graft was sutured in a continuous fashion with suture buttressed with two strips of Teflon felt, and the distal anastomosis was done in the usual manner opposite the ostium of the iliac arteries. The operation was performed without difficulties, and the patient was extubated 48 hours after operation. Because of respiratory and cardiac depression the patient was reintubated, and he died 12 days after the operation due to severe anoxic cerebral-related disturbances. The vascular graft was performing correctly at any time.

Postmortem examination showed a chronic aortic dissection starting in the left subclavian artery in association with a repaired

atherosclerotic infrarenal AAA. The graft was correctly placed. In retrospect, our patient had a remote nondiagnosed type B aortic dissection in association with a ruptured atherosclerotic AAA.

I agree with Roberts and Roberts [1] regarding the infrequent association of combined AAA and thoracic aortic dissection in the same patient and the scarcity of reports about this subject. Our case has some resemblances with the cases reported by Roberts and Roberts [1, 2] and has recently been published [3]. I believe this report can be useful for readers interested in aortic surgery and stress the importance of keeping in mind the eventuality of the association of AAA and thoracic aortic dissection, considering, from theoretical grounds, the possibility of an increasing number of cases in the future, and the necessity and recommendation of full investigation (computed tomographic scanning) of the whole aorta before an aortic operation.

Treatment of AIDS-Related Bronchopleural Fistula by Pleurectomy

To the Editor:

Crawford and associates [1] have emphasized the advantages of early and aggressive surgical treatment of spontaneous pneumothoraces and persistent bronchopleural fistula associated with acquired immunodeficiency syndrome (AIDS). I share their enthusiasm for early surgical intervention, which includes a parietal pleurectomy and diaphragmatic abrasion in addition to closure of the bronchopleural fistula. This approach has evolved because patients with AIDS are surviving longer and thus are at risk for development of multiple recurrent pneumothoraces [2]. This is illustrated by a representative case demonstrating the progressive course of *Pneumocystis carinii* pneumonia associated with AIDS.

The patient was a 34-year-old man first seen in June 1989 after suffering a spontaneous left pneumothorax following a bout of violent coughing. The patient had a history of AIDS, *Pneumocystis carinii* pneumonia treated with aerosolized pentamidine, disseminated histoplasmosis, and pancytopenia. A chest tube was placed with reexpansion of the lung, but a bronchopleural fistula persisted for 14 days despite attempts at chemical pleurodesis. He was taken to the operating room, and closure of the bronchopleural fistula along with pleurectomy was performed. Chest radiograph after this revealed expansion of the lung with minimal cystic changes of *Pneumocystis carinii* pneumonia (Fig 1). In August 1989 he had a right pneumothorax, which was treated with thoracotomy, closure of the fistula, and pleurectomy. Chest radiograph taken at this time revealed progression of the pneumatoceles bilaterally. The patient was admitted to the hospital in

Fig 1. Chest roentgenogram after pleurectomy and closure of bronchopleural fistula.

December 1989 for the last time with marked progression of the pneumatoceles (Fig 2), pancytopenia, and overwhelming sepsis. He died January 8, 1990, approximately 6 months after his initial presentation.

Much has been written concerning the association of *Pneumocystis* pneumonia and AIDS. *Pneumocystis carinii* pneumonia in association with AIDS seems to be more prone to the development of pneumothoraces, probably due to the prolonged course

Fig 2. Chest roentgenogram showing marked progression of pneumatoceles.

of infection and the cytotoxic effects of human immunodeficiency virus directly on the pulmonary parenchyma [3]. These pulmonary changes can be progressive and are not avoided by aerosolized pentamidine administration. The pentamidine, in fact, is thought possibly to be associated with a higher incidence of pneumothorax due to the uneven distribution of the drug, with subsequent progression of the disease in the lung apices [4].

The case presented illustrates what can be a virulent replacement of lung parenchyma with pneumatoceles due to *Pneumocystis carinii* pneumonia. These pneumatoceles are prone to rupture with resulting recurrent pneumothoraces, and are not confined anatomically to the apices. Because of the often progressive course of the lung destruction associated with AIDS and *Pneumocystis carinii* pneumonia, I believe that thoracotomy should be considered with the first spontaneous pneumothorax. The operation should include closure of the bronchopleural fistula and attempts to induce pleural symphysis through aggressive parietal pleurectomy. This approach will give the greatest chance of avoiding future pneumothoraces and subsequent operations, should the pneumatoceles due to the *Pneumocystis carinii* increase.

Staged Expanding Pulmonary Artery Band

To the Editor:

We have read Warren and associates' article [1] in *The Annals of Thoracic Surgery* with great interest. The concept, though, of a simple band closed with several sutures with a controlled distance in between in such a way that the outer suture holds the banding at an increased diameter when the inner one ruptures is not new. We published a study of this concept in a series of articles between 1988 and 1990 [2-4]. We used a regular 4-mm-wide Dacron tape with a radiopaque elastic rubber string in it, and closed it with several single transverse mattress sutures of 5-0 polypropylene. Thus no new engineering was introduced into the banding concept, eg, as in the work of Vince and associates [5, 6]. We evaluated the method in vitro [2] and in a canine experimental study [3], in which the pulmonary artery was banded and long-term follow-up was performed.

Topics in the discussion of Warren and associates' article [1] were the need for human clinical trials, the fact that there is no definite physician's control over the timing of the release of the sutures, suggestions of balloon dilation of the band, and concern about the role scar tissue may play in dilatability. We would like to point out that these very concepts have already been pursued in our institution as mentioned above. Our clinical experience was published 3 years ago [4]; balloon dilation makes the inner

suture rupture. Scar tissue has been no problem in humans. The pulmonary artery does widen. The gradient is being reduced, and the lung flow increased correspondingly.

Reply

To the Editor:

I was unaware of the *Cardiovascular and Interventional Radiology* literature concerning this subject; however, in our study, we attempted to develop a technique in which no further intervention would be necessary such as balloon dilation or adjusting the volume of a reservoir. Doctor Bjørnstad and associates' technique of balloon dilation would certainly be an advantage if our technique failed to expand the band with systemic pulmonary artery pressure. We were also gratified to see that Dr Bjørnstad and associates had no problems with scar tissue in human trials, and hopefully our technique will not require balloon dilation if the band expands properly.

Transthoracic Balloon Pumps

To the Editor:

I read with interest the article by Hazelrigg and associates [1] reporting their transthoracic intraaortic balloon pump (IABP) insertion techniques and impressive results. It is noteworthy, however, that they inserted the IABP by the transthoracic route

almost twice as often as they did by the femoral route in their overall series during this interval.

My colleagues and I have reserved transthoracic IABP insertion for only those patients who have major lower extremity ischemic disease or in whom we have been unable to place the IABP by the femoral route. However, when necessary, we have used a technique similar to that described by Hazelrigg and associates. Like them, we insert the balloon through a stab wound between pledged sutures and advance it into the proximal descending aorta. Previously, we obtained an intraoperative roentgenogram, but the radiopaque tip in most IABPs shows only the distal extent of the balloon, which we have generally attempted to place near the diaphragm, with monitoring of the left radial pulse. More recently, we have used transthoracic echocardiography for localization of the balloon.

There is one minor technical modification that we have found useful for IABP removal. At the time of insertion, rather than tying the pledged pursestrings, we have snared those sutures around the shaft of the IABP, using the snares themselves to help secure the catheter and to prevent subsequent migration with pulsation. This is basically the same technique we use for standard aortic cannulation for cardiopulmonary bypass. The suture protruding from the end of the snare is turned down along the shaft of the snare and secured with a large Weck clip. This has allowed us to leave those snares in the chest while the IABP is in place. As described by Hazelrigg and associates, the shaft of the IABP catheter exits from the lowermost portion of the sternotomy incision.

When the time comes for IABP removal, the clips on the snare can be released, and the already placed pursestring can be tied after the balloon has been removed, similar to the way in which we decannulate the aorta at the end of standard cardiopulmonary bypass. This eliminates associated blood loss or the need for application of a partial occlusion clamp, a particular advantage in the patient who frequently has a number of proximal coronary bypass grafts or a diffusely diseased aorta.

Dr Hazelrigg and his co-authors are to be congratulated on their excellent series.

John Gibbon and His Heart-Lung Machine*

To the Editor:

This letter is directed to the attention of your subscribers who have purchased or read my book *John Gibbon and His Heart-Lung Machine* (Philadelphia: University of Pennsylvania Press, 1991). Doctor Bernard J. Miller, who worked with Dr Gibbon, has recommended the following changes. These changes will be incorporated into any future editions of the book, by arrangement with the University of Pennsylvania Press.

1. Doctor Miller pointed out that I had not cited the source for the quotation on page 112, "Animal experiments using the

* Reprinted from *Tex Heart Inst J* 1992;19(3):245, by permission.

Model II were only moderately successful," and for the description of the laboratory respirator. The source for this information is: Miller BJ. The development of heart lung machines. *Surg Gynecol Obstet* 1982;154:403-14. I regret this unintentional omission.

2. The respirator using negative pressure to assist expiration, as described on page 112, should be attributed to Dr Miller.[†] Doctor Miller made modifications to the animal-laboratory respirator that enhanced gas exchange and contributed to lower mortality rates following its adoption. A full description of Dr Miller's respirator can be found in: Miller BJ. A respirator for laboratory animals utilizing compressed air and suction. *Surgery* 1957;42:722-5.
3. Doctor Miller recommends that the section on pages 166-7 (involving "Dr. X") be deleted.

In these instances, Dr Miller's wishes will be carried out.

Pericardioperitoneal Shunt for Persistent Effusions

To the Editor:

We read with interest the article by Molnar and Jeyasingham [1]. In the last 2 years we performed a similar procedure on 7 patients with persistent pericardial effusion, and achieved excellent palliation. The only modification in our technique is that after excising the pericardial patch, we run a continuous Vicryl (Ethicon Ltd, Edinburgh, UK) suture around the edge of the window joining the pericardial and the peritoneal edges. We pass a drain through the window, which exits through the abdominal wall. This drain is removed when the amount of drainage is minimal. None of these patients had clinical evidence of recurrence of the effusion.

It has been shown [2] that the success of a window is dependent on the inflammatory fusion of the pericardium to epicardium and not maintenance of a window, and that tube decompression should be maintained only until fluid output is minimal to allow apposition and fusion of the two surfaces. Therefore, we do not see the need to maintain a permanent drain in the site;

[†] In connection with item #2, a copy of a letter of confirmation from Dr George J. Haupt will be placed on file at the University of Pennsylvania Press offices before implementation of the recommended change.

indeed, it may not be necessary to form a pericardioperitoneal connection at all.

Reply

To the Editor:

The modification in pericardioperitoneal shunt procedure proposed by Izzat, Prendergast, and Thorpe is sensible and advisable in benign cases. One has to keep in mind, however, that differences exist in the adhesion and apposition forming tendencies between the thoracic and abdominal cavities. The drain was used to keep open the peritoneal face of the communication hole. Our main goal was to avoid external drainage and consequent decreased quality of life of patients with limited life expectancy.

The procedure theoretically could be improved by using a circular stapler for creation of a persistent pericardioperitoneal communication. Another possibility is to use a laparoscopic technique in the same manner as the pericardiopleural window is done [1].

CLASSIFIED ADVERTISEMENTS

Classified advertisements for positions wanted or available must relate only to the thoracic or cardiovascular surgical specialties. Display space (minimum, ¼ page) is also available through Art Carlucci, Elsevier Science Publishing, 655 Avenue of the Americas, New York, NY 10010 (telephone: (212) 633-3806; facsimile: (212) 633-3820). All advertisements are subject to the approval of the editor, and material deemed inappropriate for publication in *The Annals* will be rejected. If anonymity is desired, please indicate this at the time of submission and a code number will be assigned. All responses received will remain confidential in the publisher's office and will be conveyed to the advertiser shortly after receipt. The charge for all classified advertising is **\$1.60 per word per insertion, minimum 20 words**. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. **There is an additional fee of \$25.00 per insertion for box number advertisements.** The copy deadline is 7 weeks prior to publication, eg, for the March issue, copy should be received by the 1st of January. Advertisement orders should be for a maximum of 6 months; advertisements may be renewed for up to 6 months at a time. Advertisement copy should be typed double-spaced and mailed in duplicate to: *The Annals of Thoracic Surgery*, Desk Editorial, Classified Advertisements, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010 (facsimile: (212) 633-3853). Make *nonrefundable* check payable to Elsevier Science Publishing Co, Inc.

Please note that *The Annals* does not function as a placement service and cannot provide information on advertised positions. When answering advertisements, please write individually to each advertiser you wish to contact, using the address given in the advertisement. To respond to an anonymous advertisement, write to Box Number, *The Annals of Thoracic Surgery*, Elsevier Science Publishing, 655 Avenue of the Americas, New York, NY 10010.

SITUATIONS AVAILABLE

Thoracic and cardiovascular surgeon with emphasis on pediatric/neonate cardiac surgery and cardiac transplantation is needed by a full-service thoracic and cardiovascular surgery group on the west coast. Must have ABTS certification. Excellent salary and benefits package. Please respond with curriculum vitae and case list.

Please respond to Box 702. 702K/D

Cardiothoracic surgeon, board certified/eligible, wanted to join established practice in northwest Indiana (very near Chicago). Excellent salary. Please respond with curriculum vitae.

Please respond to Box 723. 723L/G

Cardiothoracic vascular surgeon, board certified or board eligible, to join well-established, busy one-man private practice in Midwest. Salary leading to partnership. Please send CV and references.

Please respond to Box 743. 743A/L

Thoracic/cardiovascular surgeon: three-man group in suburban New York doing general thoracic and peripheral vascular surgery desires new graduate of approved thoracic program with training in vascular surgery. Please respond with CV.

Please respond to Box 758. 758L/B

Cardiovascular and thoracic surgeon: BE/BC wanted to join an established, busy private practice in the Midwest. Peripheral

vascular expertise desirable. Recent graduate of a university program preferred. Salary leading to full partnership. Please respond with curriculum vitae and references.

Please respond to Box 763. 763I/B

Cardiothoracic surgeon, BE/BC, to join busy 1-man private practice in mid-Michigan. Excellent opportunity. Salary leading to partnership. Please send CV and references.

Please respond to Box 779. 779J/C

Thoracic and vascular surgeon, BE/BC, to join active (noncardiac) thoracic and vascular practice in central New Jersey. Please respond with curriculum vitae and details of experience. Salary leading to full partnership.

Please respond to Box 795. 795K/C

Cardiovascular and thoracic surgeon: Excellent opportunity for a board certified/eligible university-trained surgeon to join a new, growing department in a metropolitan New York community. Academic/private practice setting with excellent compensation. Experience in electrophysiologic surgery, artificial devices, and transplantation helpful. Please respond with curriculum vitae.

Please respond to Box 799. 799L/E

Cardiothoracic and vascular surgeon, board certified, board eligible to join an expanding three-man practice in the Rocky Mountain region. Please send CV and references.

Please respond to Box 802. 802L/E

South of Boston: Two experienced thoracic surgeons in very busy private practice offer employment and partnership opportunity for third. Ideal location 20 miles south of Boston offers educational and cultural advantages of an urban environment with options for country or suburban living. Excellent salary and benefit package, leading to full partnership. If BC/BE, please send CV.

Please respond to Box 805. 805L/E

General thoracic surgeon. The Massachusetts General Hospital and Harvard Medical School seek a highly qualified clinician, teacher, and scientist in general thoracic surgery. Training and experience in airway surgery and esophageal surgery required. Appointment would be at the rank of Instructor or Assistant Professor of Surgery at Harvard Medical School, depending upon qualifications.

Please reply with curriculum vitae and bibliography to Hermes C. Grillo, MD, Chief of General Thoracic Surgery, Massachusetts General Hospital, Boston, MA 02114. Harvard Medical School and Massachusetts General Hospital are affirmative action/equal opportunity employers. Women and minority candidates are encouraged to apply. 806L/B

The Division of Thoracic and Cardiovascular Surgery at the University of New Mexico School of Medicine in Albuquerque is seeking applications for a full-time faculty position at the Assistant/Associate Professor level for July 1993. We are looking for an individual with excellent skills in adult cardiac surgery and with specialized training in cardiac transplantation. The candidate must be board eligible or certified and have strong interest in research and teaching. This is an excellent opportunity for an individual interested in academic achievements as well as a good clinical experience.

Please forward curriculum vitae and three letters of recommendation to Jorge A. Wernly, MD, Chief, Division of Thoracic and Cardiovascular Surgery, University of New Mexico Medical Cen-

ter-ACC2, Albuquerque, NM 87131. An affirmative action/equal opportunity employer. 809L/C

Cardiothoracic/vascular surgeon: board certified in general surgery and BE/BC in thoracic surgery to join strong cardiovascular practice in western Pennsylvania. Major need for thoracic and vascular surgeon; cardiac surgery if desired. Excellent benefits. Detailed CV must accompany response. All replies treated confidentially.

Please respond to Box 811. 811L/E

Cardiovascular thoracic surgeon—board certified/board eligible and recently trained to join an established, busy, dynamic and expanding private practice in northwest Indiana. The sphere of practice is approximately 30 minutes from downtown Chicago. Guaranteed excellent starting salary with progressive future growth and comprehensive corporate fringe benefit program leading to partnership for the right individual.

Write including CV and details of experience and capabilities to PO Box 3066, Munster, IN 46321. 814A/C

Cardiac surgeon to join established, two-man private practice in Chicago and its suburbs. Salary leading to full partnership. Excellent facilities and experienced associates.

If interested, please respond to Box 815. 815A/C

Experienced and board certified cardiothoracic surgeon needed to join an established group of thoracic and vascular surgeons in a newly approved cardiac surgery program in a community hospital. Responsibilities include coordinating and leading the cardiac surgical team of this group practice. Competitive package.

Please respond to Box 817. 817A/F

Director—Cardiothoracic Surgery: Board certified cardiac surgeon needed to coordinate and direct a new cardiac surgery program in a community hospital in association with an established group of surgeons. Strong community and medical staff support will assure a successful program. Attractive financial package.

Please respond to Box 820. 820A/F

Noncardiac thoracic and vascular surgeon, BE/BC, to join established one-man private practice on Florida's southeast Gold Coast. Send CV and details of experience.

Please respond to Box 822. 822A/C

Thoracic and vascular surgeon, BC/BE, needed for community practice in Northeast. No cardiac surgery. Please send CV.

Please respond to Box 824. 824A/B

Cardiothoracic and vascular surgeon to join a well-established three-man adult CV practice in California's Central Coast. Applicant must be BE/BC. Recent graduate of university program preferred. Please respond with CV.

Please respond to Box 825. 825A/B

Cardiovascular surgeon wanted to join three surgeons in an established adult cardiac, thoracic, and vascular surgery practice in north central Texas. Must be board certified/eligible. Salary plus benefits with full partnership available. Please send resume and references.

Please respond to Box 828. 828A/C

Faculty/academic position: The Division of Cardiothoracic Surgery, University of Washington, is seeking a BC/BE, adult cardiothoracic surgeon. The individual will have a dual appointment at University Medical Center and the Veterans Administration Medical Center. He/she will be responsible for continuing the VA clinical, educational, and research programs. He/she should have

demonstrated a strong clinical cardiac surgery background and commitment to education and research. AA/EOE.

Send complete curriculum vitae to Edward D. Verrier, MD, Division of Cardiothoracic Surgery, RF-25, University of Washington, Seattle, WA 98195. 834A/B

Academic general thoracic surgeon: The Division of Cardiothoracic Surgery and the Section of Thoracic Surgery invites applications and nominations for a faculty position in general thoracic surgery at the University of Washington. Prospective candidates should be American Board of Thoracic Surgery eligible or qualified as of July 1, 1993, have demonstrated excellence in clinical surgery and research, and possess a commitment to teaching. Preference will be given to those who have broad experience in general thoracic surgery including lung transplantation. The successful candidate will be involved in the clinical programs at the University of Washington Medical Center, Harborview Medical Center, and Seattle Veterans Administration Hospital in Seattle as well as becoming actively involved in the Lung Transplant Program, the Cardiothoracic Surgery Laboratory, and in participating in the Thoracic Surgery clinical trials.

Applicants should have their curriculum vitae sent to the following address: Douglas E. Wood, MD, Chief, Section of Thoracic Surgery, University of Washington, Division of Cardiothoracic Surgery, SA-25, Seattle, WA 98195. University of Washington is an equal opportunity, affirmative action employer. 836A/B

Cardio-thoracic surgeon, board certified/eligible, wanted to join established practice in Finger Lakes area of New York State. Private practice setting leading to full partnership in group with excellent case load. Community has very strong private practice hospital setting.

Please send CV to James E. Vaughan, MD, 600 Ivy St, Elmira, NY 14905. 838B

Thoracic and vascular surgeon, BC/BE, to join busy, congenial surgical group in Connecticut. Varied and challenging practice at private and university hospitals in close proximity. Excellent salary and benefits with partnership potential. Send CV.

Please respond to Box 839. 839B/E

Cardiothoracic surgeon, BE/BC to join 2-man private practice located in Southeast. Large volume general thoracic, increasing cardiac surgery volume. Prefer recent graduate with training in adult cardiac surgery.

Please respond to Box 840. 840B/C

Cardiovascular and thoracic surgeon to join busy two-man practice of adult cardiac, thoracic, and vascular surgery seeking recent graduate of American training program. Located in beautiful East Texas, surrounded by lakes and national forests—great lifestyle but only 100 miles north of Houston. Well-trained FMGs will be considered.

Please respond to 609 S John Redditt, Lufkin, TX 75901. 841B/C

Cardiothoracic surgeon: The Miriam Hospital is seeking a cardiothoracic surgeon to join the Department of Surgery, Division of Cardiothoracic Surgery. The individual will function as the Associate Director of this division. The successful candidate must qualify for a full-time medical faculty position at the rank of Assistant or Associate Professor in the Brown University School of Medicine. Minimum requirements include board certification in general and cardiothoracic surgery or eligibility for the latter if training is recently completed. A record of scholarly achievement and national recognition commensurate with the level is expected. A strong clinical background, excellence in patient care and teaching are required. It is expected that approximately one third of the candidate's time will be devoted to teaching. Remaining time will be spent in clinical care and/or administration. The

Miriam Hospital is an equal opportunity, affirmative action employer and encourages applications from protected and minority groups. Applications are expected within 6 weeks of the date of this publication. Screening will begin on that date and continue until a successful candidate is identified or the search is closed.

Please forward curriculum vitae or recommendations to A. Gerson Greenburg, MD, PhD, Chair Person, Search Committee, The Miriam Hospital, 164 Summit Ave, Providence, RI 02906. 842B/D

Emory University Department of Surgery, Division of Cardiothoracic Surgery, Atlanta: currently seeking candidate for faculty at assistant professor level in adult cardiac surgery with a particular interest in diseases of the aorta. Candidates must be board certified in general surgery and board certified or eligible in thoracic surgery and have a strong academic and research focus. Women and minorities are encouraged to apply.

Please submit CV and letters of recommendation to Robert A. Guyton, MD, Chief, Division of Cardiothoracic Surgery, The Emory Clinic, 1365 Clifton Rd, NE, Atlanta, GA 30322. Emory University is an affirmative action, equal opportunity employer. 844B

Cardiothoracic surgeon, BC/BE, wanted to join adult cardiac surgery program in the South. Solo practice is very busy serving as regional referral center. First-rate medical facilities, liberal compensation package, and warm hospitality await you! Please send CV.

Please respond to Box 845. 845B/C

Cardiovascular surgeon, board certified/eligible, wanted to join two surgeons in an established cardiovascular program in the southeastern USA. Must have experience in adult cardiac, thoracic, and vascular surgical procedures. Salary/full partnership negotiable. Please send resume.

Please respond to Box 846. 846B/C

SITUATIONS WANTED

Cardiothoracic surgeon, 35 years old, university trained, board certified with two years busy private practice experience. Seeks opportunity with new program, individual, or group in the Southeast.

Please respond to Box 757. 757J/C

FELLOWSHIPS

Surgical residents/fellows—Clinical residency/fellowship positions available in adult and pediatric cardiothoracic surgery. Large volume of cases. New Jersey license required. Excellent salary and benefits.

Please contact Lynn B. McGrath, MD, Chairman, Department of Surgery, Deborah Heart and Lung Center, 200 Trenton Rd, Browns Mills, NJ 08015; (609) 893-6611, Ext 359. 653A/B

Fellowship in a very busy pediatric cardiovascular surgery center is available July 1993. Experience includes performing surgery for very complex congenital heart disease and participation in ongoing educational and research activities. Illinois license or equivalent required. Salary and benefits exceed \$45,000.

Please respond to the Division of Pediatric Cardiac Surgery, The Heart Institute for Children/Christ Hospital and Medical Center, 4440 West 95th St, Oak Lawn, IL 60453. 821A/B

Cardiovascular surgical fellow: Department of Cardiovascular Surgery, San Francisco Kaiser-Permanente Medical Center, offers a one-year clinical fellowship in cardiovascular surgery beginning July 1, 1993. Applicants must be ABS BC/BE. High volume, excellent salary and benefits.

Please send CV and direct questions to M. Terry McEnany, MD, Chief, Department of Cardiovascular Surgery, Kaiser-Permanente Medical Center, 2350 Geary Blvd, San Francisco, CA 94115; (415) 202-3800. 826A/D

Cardiothoracic surgical fellowship—Allegheny General Hospital is seeking qualified candidates for a one-year, nonaccredited fellowship position in cardiothoracic surgery, available July 1, 1993, through June 30, 1994. The program enjoys a large volume of adult cardiac surgery and thoracic surgery cases, including thoracoscopy, esophageal and pulmonary resections, in addition to a strong research program. The program is assisted by seven physician assistants.

Please send a CV and letters of recommendation to George J. Magovern, MD, Professor and Chairman of Surgery, Allegheny General Hospital and the Allegheny Campus of the Medical College of Pennsylvania, 320 E North Ave, Pittsburgh, PA 15212. 827A/D

Cardiothoracic research fellowship: The Division of Cardiothoracic Surgery at the University of Washington is seeking research fellows for 1-2 years. Active lab research interests include the vascular and molecular biology of ischemia/reperfusion, heart/lung transplantation, and myocardial protection. Surgical residents preferred, prior research experience not required.

Interested applicants should send CV to Ed Verrier, MD, Associate Professor and Chief, Division of Cardiothoracic Surgery, SA-25, University of Washington, 1959 NE Pacific Ave, Seattle, WA 98195. 832A/B

Senior fellow position available for 1 year: Cardiothoracic surgical residency program has 1-year fellowship at senior level to begin July 1, 1993. High-volume program offers excellent experience in electrophysiologic surgery, valve repair, cardiac transplantation as well as standard cardiac surgical procedures. Salary equivalent to senior cardiac resident level.

Apply to Edward D. Verrier, MD, Chief, Cardiothoracic Surgery, University of Washington Medical Center, Department of Surgery, SA-25, Seattle, WA 98195, USA; (206) 685-3370. 833A/B

Thoracic and cardiovascular surgery fellowship: One-year fellowship available beginning July 1, 1993, in the Department of Surgery, Baylor College of Medicine. Based at The Methodist Hospital, fellows will participate in a broad range of cases. In addition to routine adult cardiovascular and thoracic surgery, areas of special interest include major thoracic aneurysm surgery, arrhythmia surgery, transplantation, thoracoscopy, general thoracic and vascular surgery. Clinical and laboratory research opportunities are also available.

Please send inquiries with curriculum vitae to Gerald M. Lawrie, MD, One Baylor Plaza, Department of Surgery, Houston, TX 77030. Baylor College of Medicine is an equal opportunity/affirmative action/equal access employer. 843B

Developments affecting the diagnosis, treatment and prevention of infectious diseases occur frequently and in many fields of study. Staying abreast of these changes is more and more difficult—unless you're a reader of **Infectious Diseases Newsletter**.

Whether you're a physician, nurse, or lab professional, **Infectious Diseases Newsletter** is your remedy for this situation. As a subscriber you will receive brief and to-the-point original articles and case studies covering the latest international news and advances concerning infectious diseases.

The newsletter's original articles give you distilled information on new and newly resistant infectious diseases and practical ideas you can apply directly to your work. The newsletter's case studies help you choose appropriate therapy for current patients and prepare you for diagnosing symptoms and diseases you may encounter in the future.

Infectious Diseases Newsletter also keeps an eye on other publications for you. You'll find selected excerpts from recently published articles in *Science*, *Lancet*, *New England Journal of Medicine*, *American Review of Respiratory Disease*, *Journal of Antimicrobial Chemotherapy*, *British Medical Journal*, *Annals of Internal Medicine*, *Diagnostic Microbiology and Infectious Disease*, *Scandinavian Journal of Infectious Diseases*, and *Journal of Clinical Microbiology*.

Cardiothoracic Fellow

The Lankenau Hospital and Medical Research Center is a state-of-the-art medical teaching and research facility nestled in a beautiful, yet convenient suburban Philadelphia location. This past year we performed over 800 open heart surgeries including surgery for atrial and ventricular arrhythmias.

We will have a position available July 1, 1993 on our staff for a Cardiothoracic Surgical Fellow. The ideal candidate should be board eligible or certified in general surgery. Board eligible in thoracic surgery highly desired. A Pennsylvania license is a must. Clinical Fellows are welcome to apply.

Along with top of the line technology and professional colleagues, the position offers medical benefits, no city wage tax deducted and a non-smoking environment. For further information, please forward CV to: Dr. Scott M. Goldman, Chief, Division of Thoracic & Cardiovascular Surgery, c/o Personnel Department, 100 Lancaster Avenue, west of City Line, Wynnewood, PA 19096.

A Member of the Main Line Health Family of Hospitals.

Assistant Professor Cardiothoracic Surgeon

The Division of Cardiothoracic Surgery at the University of Massachusetts is expanding its academic faculty. Candidates will be expected to have an interest in developing an academic cardiothoracic practice, to participate in thoracic and general surgical residency training, and to take part in clinical and/or laboratory research.

The University of Massachusetts is an equal opportunity employer.

Please respond with curriculum vitae to: Thomas J. Vander Salm, M.D., University of Massachusetts

Medical Center,
55 Lake Avenue North,
Worcester,
MA 01655.

Cardiothoracic Surgeon

The Department of Surgery at the Dartmouth-Hitchcock Medical Center in Lebanon, New Hampshire is searching for an additional academic Cardiothoracic Surgeon at the Assistant/Associate Professor level. Candidates for this position must be BC/BE in Thoracic Surgery and should have demonstrated, by prior training and expertise, superior skills in all aspects of adult and pediatric cardiac surgery as well as general thoracic surgery. The physician will be responsible for the care of patients in an established cardiothoracic practice at The Hitchcock Clinic with privileges extended to the Veterans Administration Hospital in White River Junction, Vermont.

The successful candidate should have demonstrated a commitment to research by previous experience and publications and will have the opportunity for further academic pursuits, including the education and training of medical students and house staff physicians. The individual will be an employee of The Hitchcock Clinic and will receive an appropriate academic appointment as a member of the faculty of Dartmouth Medical School. DHMC is an AA/EO employer and is especially interested in identifying female and minority candidates.

Inquiries and resumes should be directed to Charles A.S. Marrin, M.B., B.S., Chairman, Cardiothoracic Surgery Search Committee, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire 03756, (603) 650-7390.

Lebanon, New Hampshire

Fargo, North Dakota
PHYSICIAN ASSISTANT
Cardiothoracic Surgery

Fargo Clinic MeritCare, a large multispecialty clinic affiliated with a leading tertiary hospital, is seeking experienced, certified PA's to work in Thoracic Surgery. Qualified candidates must have cardiothoracic training and experience in both the adult and pediatric population.

Fargo Clinic offers a professional, supportive environment, competitive salary, excellent benefits, and sign-on bonus.

Fargo, North Dakota, ranks fifth nationwide in the top 100 best places to live. The community is friendly, economically stable, and offers a variety of educational, cultural, and recreational activities.

Please submit your resume and work experience to:

Fargo Clinic
MeritCare
 Mona Lokken, Recruiting
 & Employment Manager
 PO Box 2067
 Fargo, ND 58123

or call toll free: 1-800-437-4010 Extension 2728

Fargo Clinic does not discriminate on the basis of disability, and is an Equal Opportunity/Affirmative Action employer.

Adult Cardiothoracic Surgeon

Four-man university-affiliated cardiovascular surgery group in private suburban practice of major midwest metropolis seeks fifth surgeon. Prefer new (93 or 92) or recent board eligible/certified graduate with impeccable credentials and experience. Expanding volume near 900 pump cases with significant thoracic and PV case load. Experience in thoracoscopy and PV surgery desired.

Excellent salary and benefits leading to partnership for the right individual.

CARDIOVASCULAR PATHOLOGY

*Official Journal of the Society
for Cardiovascular Pathology*

Editor-in-Chief:

Stephen M. Factor, MD

Cardiovascular Pathology is a quarterly journal presenting articles on topics that cover the entire spectrum of the discipline. The Journal's primary objective is to publish papers on disease-oriented morphology and pathobiology from pathologists and non-pathologist investigators in the cardiovascular field.

Subjects range from vascular pathobiology to mechanical prostheses, from molecular biology to clinical cardiac disease, from experimental ischemia to descriptive gross morphology. **Cardiovascular Pathology** also publishes timely, informative reviews on scientific areas in cardiovascular pathology, and case reports that represent significant or unique observations.

Articles recently published in **Cardiovascular Pathology** include:

- Cardiac Transplant-Associated Vascular Disease: Evolution, Immunophenotype, and Evidence of Endothelial Activation, *K. Kottke-Marchant, W.E. Newman, and N.B. Ratliff*
- Pathogenesis of a Double Rupture (Septal and Free Wall Rupture) After Acute Myocardial Infarction, *R.S. Larson, E.J. Haskel, and J.E. Perez*
- Branch Location in the Left Anterior Descending Coronary Artery and Its Relation to the Known Distribution of Early Atherosclerosis, *N.R.B. Cary, T. Biggs, and W.A. Seed*
- Transcriptional Regulation of Calcium-Activated Neutral Protease in Cardiomyocytes of Hypertensive Rats, *M.N. Kumar, P. Grammas, F. Giacomelli, and J. Wiener*
- Intimal Thickening of Peripheral Pulmonary Vein: Analysis of 139 Consecutive Autopsy Cases, *M. Sageshima, H. Masuda, K. Kawamura, and T. Shozawa*
- Further Morphological Observations on Hearts With Twisted Atrioventricular Connections (Criss-Cross Hearts), *J.W. Seo, S.J. Yoo, S.Y. Ho, H.J. Lee, and R.H. Anderson*

Cardiovascular Pathology is abstracted in CABS/Current Awareness in Biological Sciences.

WE'RE WIRED

ABOUT OUR

NEW TEMPORARY

PACING LEADS

Medtronic now has a new family of heartwires that deserve to be called temporary pacing leads.

The unique discrete electrode, which allows reliable pacing and sensing, is what makes our Model 6500 and our new smaller Atrial and Pediatric temporary myocardial pacing leads more than just generic heartwires. And the sutureless fixation coil, found only on Medtronic temporary pacing leads, allows faster, easier, less traumatic implant. Please contact your local Medtronic representative for more information about any of our complete line of Medtronic® Temporary Myocardial Pacing Leads.

From the company with over 40 years of pacing experience.

CAUTION: Federal law (U.S.A.) restricts this device to sale by or on the order of a physician. For detailed information on intended use, contraindications, precautions, and warnings, please refer to the Instructions For Use provided with the product.

SUSTAINING LIFE IN EVEN THE MOST CHALLENGING ENVIRONMENT.

THE TENTH ANNIVERSARY OF THE MONOSTRUT™ HEART VALVE MARKS A SIGNIFICANT MILESTONE IN THE CLINICAL APPLICATION OF ADVANCED TECHNOLOGY. AS WE MOVE INTO OUR SECOND DECADE OF MONOSTRUT™ IMPLANT EXPERIENCE, WE REMAIN COMMITTED TO PROVIDING YOU AND YOUR PATIENTS WITH A VALVE WHOSE OVERALL PERFORMANCE IS UNMATCHED.

THE COMMITMENT SHOWS: BECAUSE IN IMPLANT AFTER IMPLANT, THE MONOSTRUT™ HAS DEMONSTRATED FLAWLESS MECHANICAL PERFORMANCE, EXCELLENT HEMODYNAMIC RESULTS AND THE VIRTUAL ELIMINATION OF THROMBOSIS.

ONLY THE MONOSTRUT™ INCORPORATES AN INTEGRATED, ONE-PIECE DESIGN WITH A FREE-FLOATING DISC. CONTACT BETWEEN THE DISC AND VALVE FLANGE IS ELIMINATED DURING OPENING, PREVENTING STASIS.

EXPERIENCE TRUE COMMITMENT. CHOOSE THE MONOSTRUT™ HEART VALVE. IT'S THE NATURAL CHOICE WHEN NATURE IS UNABLE TO HELP ITSELF.

NOT AVAILABLE IN THE U.S.A.

*A new look at
biocompatibility.
Bentley® Duraflo® II.*

Every part of the perfusion circuit creates an environment that is hostile to your patient's blood. This hostile environment disrupts the integrity of the vascular system and stimulates blood reactions – including coagulation.

Blood reactions can effect your patient's postoperative recovery.

That's where Duraflo® II can help. By binding whole USP heparin directly to every blood contact surface, we've created a biologically active barrier between the foreign surfaces of the circuit and your patient's blood.

Duraflo® II creates a protective barrier between blood and foreign surfaces.

What's more, Baxter Healthcare Corporation, Bentley Division is the only cardiopulmonary company able to provide cannula - to - cannula biocompatibility – even on cardiotomy reservoirs. This universal protection turns a hostile environment into a friendly one.

Universal biocompatibility protection can mean fewer complications and faster recoveries.

To give your patients this kind of protection, just ask your Bentley representative about the All-In-One Tray GOLD™ BosPac®. Or contact Baxter Healthcare Corporation, Bentley Division at 17511 Armstrong Ave., Irvine, CA 92714. Phone 1.800.BEST.PAC. In Canada, 1.800.268.3993, Ext. 6478. In Europe, 31.(0).4132.86666. In Japan, (03).3237.6665.

Duraflo® II is the new GOLD™ standard of care in perfusion.

At Bentley, everything we touch turns to GOLD.™

MODUS OPERANDI

CASE AFTER CASE THE SAME M.O.

Durability proven beyond a shadow of a doubt

Fifteen years of investigation by Cohn et al.² suggests the Hancock M.O. Bioprosthesis "may actually be more resistant to structural valve degeneration, possibly by the more complete opening of this valve leaflet than the standard fabrication process in porcine bioprosthetic valves." The probability of being free from a structural valve deterioration for all patients at 12 years is 71.1% and for patients over 65 years increases dramatically to 93%.¹

An open and shut case of hemodynamics

The Hancock M.O. Bioprosthesis is designed to improve hemodynamics by replacing the right coronary cusp and its flow-impeding muscle shelf, with the non-coronary cusp from another porcine valve. A study published in *Circulation* demonstrated that smaller (size 19 and 21mm) Hancock M.O. Bioprostheses have lower gradients and larger valve areas than a comparably sized porcine valve retaining the muscle shelf.³

The valve of choice for the elderly patient with a small aortic annulus

The Hancock M.O. Bioprosthesis is the valve of choice for elderly patients who have a small aortic root as well as for those who should not take anticoagulants.¹

H. Lindberg, M.D.

An Open And Closed Case

Epicardial/mediastinal adhesions are a critical reoperative challenge, at times leading to serious inherent problems such as:

- Cardiac Damage
- Catastrophic Hemorrhage
- Increased Dissection Time

Since 1976, the GORE-TEX® Surgical Membrane material has been the only pericardial substitute to consistently facilitate cardiac reoperation by providing a reliable plane of dissection and reducing adhesion formation. This minimizes the risk of:

- Cardiac Damage
- Catastrophic Hemorrhage
- Increased Dissection Time

For further information, including current available literature and recommended implant techniques, call 800-437-8181, Dept. 6-N.
To order call 800-528-8763, Dept. 6-N.

ELITE®

Last year we introduced the 38-gram ELITE® DDD/R pacemaker.

Physicians responded by making ELITE® the world's most widely prescribed dual chamber pacemaker.

Today, the ELITE® technology has been enhanced, and it's now available in a pacemaker that is 30% smaller, the 26-gram ELITE II™.

ELITE II™ enhancements include

- ☐ separately programmable upper rates (sinus or sensor) for managing brady-tachy patients,

THE WORLD'S MOST WIDELY PRESCRIBED DUAL CHAMBER TECHNOLOGY

- ☐ the ability to do electrophysiologic studies¹ for premature electrical stimulation or burst pacing, and
- ☐ Marker Channel™ Diagrams¹ to aid interpretation of cardiac activity and pacemaker operation.

Plus, **ELITE II™** offers

- ☐ a dedicated bipolar model for use with implantable cardioverter-defibrillators,
- ☐ a proven atrial sense amplifier for superior atrial sensing, and

P E T I T E E L I T E[®]

□ 19 pacing modes for therapeutic flexibility. Coupled with our easy-to-use programmers (portable 9710A or desktop 9760) and our low-threshold, steroid eluting CapSure[®] SP leads, the ELITE II[™] pacing system is *simply more powerful*.

Of course, experience counts as well. The ELITE II[™] pacemaker is Medtronic's eighth-generation rate responsive device. Our patented sensor technology now has been implanted in nearly 300,000 patients worldwide.²

**NOW
ENHANCED IN
A PACEMAKER
THAT'S 30%
SMALLER**

And with recent studies showing the benefits of atrial-based pacing in patients with sick sinus syndrome (i.e., increased survival, reduced incidence of atrial fibrillation and congestive heart failure),^{3,4} it's no surprise that you and your colleagues are now prescribing dual chamber pacemakers for 47% of your pacemaker patients, compared to only 25% five years ago.⁵

Once you try the new ELITE II[™], we think you'll want to consider it for all your pacing patients.

SIMPLY MORE POWERFUL.

References: 1. Currently not available. Future software will allow this capability. See your Medtronic representative for availability. 2. Medtronic data on file. 3. Rosenqvist M, Brandt J, Schüller H, et al. Long-term pacing in sinus node disease: effects of stimulation mode on cardiovascular morbidity and mortality. *Am Heart J.* 1988;116(1 pt 1):16-22. 4. Santini M, Alexiou G, Ansalone G, et al. Relation of prognosis in sick sinus syndrome to age, conduction defects, and modes of permanent cardiac pacing. *Am J Cardiol.* 1990;65(11):729-735. 5. Industry Marketing Survey data.

INTENDED USE: The ELITE II™ dual chamber pacemaker is for therapeutic management of heart rate disorders when restoration of AV synchrony or the need for rate response is indicated. The DDDR, DDIR, and DMR pacing modes are for persistent sinus brady, uncontrollable brady-tachy syndrome, and sinus pause/arrest. The AAIR mode is for sinus node dysfunction and intact AV conduction. The VVIR mode is for chronic atrial flutter or fibrillation with a slow ventricular response, certain atrial or ventricular arrhythmias, or situations where it is desirable to disable the atrial channel (e.g., inexcitable atrium). See product labeling for a detailed list of intended uses for the 19 pacing modes available.

CONTRAINDICATIONS: In the presence of chronic atrial flutter or fibrillation, the DDDR, DDD, DDIR, and DDI modes may be contraindicated and atrial pacing in the DMR and DM modes is ineffective. The AAIR, AA, AAT, AOC, and AOO modes are contraindicated in the presence of AV conduct disturbances. The asynchronous pacing modes are contraindicated if competition between paced and intrinsic rhythms is likely. Do not use steroid eluting leads in patients for whom a single dose of 1.0 mg dexamethasone sodium phosphate may be contraindicated.

WARNINGS: Do not use diathermy over the pacemaker or defibrillation paddles within 12 cm of the pacemaker; damage to the pacemaker's electronic components may result. Do not use electrosurgical units within 15 cm of implanted pacing systems; this may introduce fibrillatory currents into the heart. Confirm pacemaker operation after diathermy, defibrillation, or electrosurgical procedures.

PRECAUTIONS: Electrical discharges from implantable cardioverter/defibrillators or external cardioversion may reset all models to the VVI mode and a bipolar ELITE II™ Model 7086 to unipolar pacing and sensing. If Model 7086 is implanted with IS-1 unipolar leads, polarity must remain unipolar to maintain output and sensing capability. Proper operation may also be affected by interference from certain electrical equipment. Any pacing system may fail due to random component or battery failures, lead-related problems, or eventual cell depletion.

SIDE EFFECTS: Possible side effects include, but may not be limited to, body rejection phenomena, muscle and nerve stimulation, infection, erosion of pacing system through skin, thrombosis related to venous leads, embolism, and cardiac tamponade.

See the technical manual for more detailed information.

Carpenter-Edwards® Duraflex™ Models 6625 LP and 6625-ESR *LP
Mitral Low Pressure Bioprostheses
For Single Use Only
Design

As compared to other types of prostheses, preserved porcine bioprostheses exhibit certain potential advantages: the need for long-term anticoagulation may be minimized; and although the durability of porcine bioprostheses is a limiting factor in long-term evaluation, tissue degeneration is usually progressive and asymptomatic, thereby permitting detection with proper serial follow-up in persons with valvulopathy, and elective intervention when necessary.

Models 6625 LP and 6625-ESR *LP Mitral Carpenter-Edwards® Duraflex™ Bioprostheses are comprised of porcine aortic valves that have been preserved in buffered glutaraldehyde and then mounted on flexible frames. Glutaraldehyde is shown to both reduce the antigenicity of porcine aortic valves and increase tissue stability.

The frame is designed to be flexible at the orifice as well as at the commissures. The compliance of the stent's commissure supports is intended to reduce the loading shock at the valve commissures and free margin of the leaflets. The flexibility of the orifice is intended to reduce the loading shock at the base of the leaflet. The flexible orifice concept is based on the physiology and mechanics of natural heart valves and supported experience with implantation of excised homologous.

The lightweight frame is made of Elgiloy®, a corrosion-resistant alloy, chosen because of its superior spring efficiency and fatigue-resistant characteristics.

The metal frame is covered with a porous, leached polytetrafluoroethylene cloth to facilitate tissue ingrowth and encapsulation. The leaflet orifice is contoured to support the right coronary cusp of the porcine valve. The commissure supports are not equivalent to conform to the anatomical configuration of the porcine aortic valve. The stent ring has a soft, silicone-rubber insert that is covered with a porous, seamless polytetrafluoroethylene cloth. The compliant nature of the stent ring facilitates coaptation between the valve and an often irregular or calcific tissue bed.

The porcine aortic valves are fixed in buffered glutaraldehyde, and then mounted on cloth-covered frames. After mounting, the valves are tested *in vitro* to ascertain their competency and flow characteristics. After final inspection, the valves are sterilized, rinsed, and then transferred into fresh glutaraldehyde and packaged under aseptic conditions.

Low Pressure Fixation
In a study by Thomas, et al., advice that to maintain optimum mechanical properties in the fixed porcine aortic leaflet tissue, the full collagen waveform or crisp originally present in the relaxed leaflet tissue should be retained. In addition, these studies show that the collagen waveform is sensitive to alteration at fixation pressures as low as 4 mm Hg. Edwards CVS Division has developed a process to fix porcine aortic valves at a hydrostatic pressure less than 4 mm Hg to minimize alterations in the collagen waveform of the aortic valve tissue. Low pressure fixation of Carpenter-Edwards Duraflex™ bioprostheses is intended to increase the clinical durability of these valves; however, data regarding Carpenter-Edwards Duraflex™ bioprostheses are insufficient to demonstrate that durability has been increased by this preparation technique or that calcification has been reduced.

Indications
Bioprostheses are indicated for use in patients suffering from valvular heart disease. Mitral valvular heart disease is a condition involving any of the following: obstruction of the heart valve or stenosis; leakage of the valve, known as regurgitation or insufficiency; and combination of the two, sometimes referred to as mixed disease or combined lesions. Valvular heart disease may be caused by any number of factors, including congenital abnormalities, infection by various microorganisms, degenerative calcification, rheumatic heart disease, and rupture or dysfunction of the mitral subvalvular mechanism secondary to myocardial infarction.

Bioprostheses are used particularly in those patients for whom long-term anticoagulation is contraindicated or who may be difficult to maintain on anticoagulation therapy.

The Carpenter-Edwards Duraflex™ bioprostheses is intended for use in patients whose mitral valvular disease is sufficiently advanced to warrant replacement of their natural valve with a prosthesis. It is also intended for use in patients with a previously implanted mitral valve prosthesis which is no longer functioning adequately and requires replacement. In the latter case, the previously implanted prosthesis is surgically excised and replaced by the replacement prosthesis.

Warnings
For Single Patient Use Only

In the presence of conditions affecting calcium metabolism or when calcium containing chronic drug therapies are used, the use of a mechanical prosthesis as an alternative should be considered. This is also true in patients under 20 years of age, in patients on a high calcium diet, and in patients who are on antidiuretic hemodialysis.

The decision to use a tissue valve must ultimately be made by the physician on an individual basis after carefully evaluating the short- and long-term risks and benefits to the patient, and considering alternative methods of treatment. The overall durability, especially long-term, has not been established for bioprostheses.

Serious complications, sometimes leading to replacement of the valve and/or death, may be associated with the use of tissue valves (see Complications). A full explanation of the benefits and risks should be given to each prospective patient before surgery.

Note: Bioprostheses should be used with caution in the presence of severe systemic hypertension or when the anticipated patient longevity is longer than the known longevity of the prosthesis (See Clinical Experience).

Careful and continuous medical follow-up (at least annually by a visit to the physician) is advised so that valve-related complications, particularly those related to material failure, can be diagnosed and properly managed.

Replacement of prosthetic heart valves who are undergoing dental procedures should receive prophylactic antibiotic therapy to minimize the possibility of prosthetic infection.

Bioprosthetic heart valve recipients should be maintained on anticoagulant therapy, except where contraindicated, during the initial healing stages after implantation, approximately 2 to 3 months. Anticoagulants should then be discontinued over a period of 10 days, except in those patients for whom indefinite anticoagulant protection is indicated, i.e., in the absence of sinus rhythm and in patients with a dilated left atrium, calcification of the aortic wall or history of previous aortic thrombosis. Please refer to the most recent Clinical Experience attachment for data on anticoagulation relating to these valves. The appropriate anticoagulation therapy must be determined by the physician on an individual basis.

Adequate rinsing with physiological saline, as described in the Technique section, is mandatory before implantation to reduce the glutaraldehyde concentration. No other solutions, drugs, chemicals, antibiotics, etc. should ever be added to the glutaraldehyde or rinse solutions, as irreparable damage to the leaflet tissue, which may not be apparent under visual inspection, may result.

Carpenter-Edwards Duraflex™ bioprostheses must be kept moist at all times. Drying out will cause irreversible damage to the leaflet tissue. To prevent drying out during implantation, the valves should be irrigated periodically on both sides with sterile physiological saline.

Passing diagnostic catheters and transvenous pacing leads across Carpenter-Edwards® Duraflex™ bioprostheses could damage the valve. Consequently, it is recommended that these procedures be avoided.

Both the valve and glutaraldehyde storage solution are sterile. The outside of the jar is not sterile and must not be placed in a sterile field. Furthermore, the valve and container should never be subjected to sterilization procedures involving ethylene oxide, propylene oxide, steam, or irradiation.

Storage between 4°C (39°F) and 25°C (77°F) is recommended; however, care should be exercised to avoid freezing or extreme heat, which may damage the valvular tissue.

Glutaraldehyde may cause irritation of the skin, eyes, nose and throat, and may also cause skin sensitization. Avoid prolonged or repeated contact or prolonged breathing of the vapor. Use only with adequate ventilation. In the event of contact with the eyes, seek medical attention.

Surgical Precautions
The models 6625 LP and 6625-ESR *LP Duraflex™ mitral valves are unapproved for indications other than mitral valve replacement.

Complications

As with all prosthetic heart valves, serious complications, sometimes leading to death, may be associated with the use of these valves. In addition, complications due to individual patient reaction to an implanted device, or to physical or chemical changes in the components, particularly those of biological origin, may occur at varying intervals (hours or days) necessitating reoperation and replacement of the prosthetic device.

Complications associated with the use of Carpenter-Edwards Duraflex™ bioprostheses, compiled from the literature and from reports received through the computerized tracking system in accordance with the United States (Federal) regulations establishing Good Manufacturing Practices section 820.198, include stenosis, regurgitation through an incompetent valve, perivalvular leak, endocarditis, hemolysis, thromboembolism, thrombotic obstruction, bleeding related to the use of anticoagulant therapy, ventricular perforation by suture points, looped sutures, and malfunctions of the valve due to distortion at implant or physical or chemical deterioration of valve components. Types of tissue deterioration include infection, calcification, dislodging, perforation, suture erosion, instrument trauma, and leaflet or suture wall detachment from the valve suture points. These complications may present clinically as abnormal heart sounds, shortness of breath, exercise intolerance, dyspnea, orthopnea, ascites, fever, arrhythmias, hemorrhage, transient ischemic attack, stroke, paralysis, low cardiac output, pulmonary edema, congestive heart failure, cardiac failure, and myocardial infarction.

Note: Based on reports in the literature on tissue valves, there appears to be an increased incidence of leaflet calcification in patients under the age of 20. In this regard, animal research studies show that a high systemic calcium level can lead to early calcification. Furthermore, at least one published report describes a potential relationship between the consumption of dairy calcium supplements and early leaflet calcification in an adult. When feasible, repeated intravenous injections containing calcium should be avoided during the postoperative period, and excessive milk or dairy product consumption should be avoided in children. There are no clinical data presently available demonstrating increased resistance of Carpenter-Edwards Duraflex™ bioprostheses to calcification as compared to other commercially available porcine valves.

See package insert accompanying product for a full discussion of warnings, contraindications, complications and postoperative information.

Caution: Federal (USA) law restricts this device to sale by or on the order of a physician.

Baxter International Inc. is the owner of the following US Patents, one or more of which covers the products described herein: 4,063,129; 4,372,703; 4,433,855. Patent numbers in foreign countries supplied upon request.

Baxter Healthcare Corporation, Edwards CVS Division
Irvine, CA 92714-1500 USA

WE IMPROVED ON NATURE THE ONLY WAY POSSIBLE. WE PRESERVED IT.

At Baxter Healthcare Corporation, Edwards CVS Division, we realize that nature has been making heart valves longer than we have.

So, when developing our low pressure porcine valve, we tried to keep it as natural as possible. To retain the original collagen waveform.

To preserve the leaflet flexibility. To incorporate a stress absorbing wire frame.

*Fresh (unfixed)
porcine tissue.*

*Low Pressure
(~ 2 mmHg) fixed
porcine tissue.*

*High Pressure
(>4 mmHg) fixed
porcine tissue.*

And to create a valve with the potential for increased durability.

The result is the Carpentier-Edwards® Duraflex™ low pressure fixed bioprosthesis. The only low pressure fixed mitral tissue valve in America.

For a brochure, contact Baxter Healthcare Corporation, Edwards CVS Division at 17221 Redhill Avenue, Irvine, CA 92714-5686 or call (800) 424-3278.

And find out why the Duraflex™ valve is the natural choice.

We call it Hemaflex.TM You'll call it standard operating procedure.

Introducing Hemaflex. It's the new, pure collagen hemostat from the makers of Avitene[®] (MCH). If you perform cardiovascular or cardiothoracic surgery, Hemaflex should be a part of your standard operating procedure.

- When wrapped around a vessel, Hemaflex has not been reported to have a stenotic effect, unlike other topical hemostatic agents.

- Hemaflex is effective in treating bone and soft tissue sites such as sternotomies and synthetic graft anastomoses.

- Hemaflex stops bleeding fast, unlike mechanical barriers, because it is pure collagen. It triggers the body's own

blood-clotting response and is absorbed easily.

- Anticoagulation treatment does not interfere with the potent actions of Hemaflex.

- Hemaflex is easy to handle and flexible enough to wrap around vessels.

So find out for yourself why we believe Hemaflex is the ideal choice for cardiovascular and cardiothoracic

procedures. Call us today at 1-800-451-4716 (in Mass., 617-938-9328), and ask for your free sample.

*To provide a place for ALL thoracic surgeons to relate experiences which
will help other practicing thoracic surgeons give better patient care.*

Herbert Sloan, MD

FROM BICARBON ON

BICARBON and Copernicus's sphere both can claim to represent a break with the past. BICARBON sets a new standard for heart valves in terms of performance and reliability: a new "system of values" that everyone will have to reckon with from now on.

THE ANNALS OF THORACIC SURGERY

INFORMATION FOR AUTHORS

Thomas B. Ferguson, MD
Editor, *The Annals of Thoracic Surgery*
3108 Queeny Tower
Barnes Hospital Plaza
St. Louis, MO 63110-1041
(314) 361-6084 FAX: (314) 367-0585

The Annals of Thoracic Surgery publishes original papers on topics in thoracic and cardiovascular surgery. Also featured are case reports, "how to do it" articles, classics in thoracic surgery, collective and current reviews, correspondence, and book reviews. All manuscripts, correspondence, and editorial business should be sent to the above address. Guidelines for collective and current reviews are available on request.

If a manuscript is accepted for publication, certain conditions must be agreed to by all authors. These include statements regarding conflict of interest, scientific responsibility, exclusive publication, and assignment of copyright. Elsevier Science Publishing Co, Inc, will maintain records of copyright for The Society. No part of the published material may be reproduced elsewhere without written permission from the publisher.

Because of escalating postage costs, manuscripts and illustrations will not routinely be returned to the authors. The editorial office will be responsible for proper disposal of the manuscripts so that confidentiality is preserved. Manuscripts and illustrations will be returned only if requested and a self-addressed stamped (US postage) envelope provided.

Checklist

The following checklist is provided for the author's convenience. Please utilize this list to make certain the manuscript is complete when submitted. Incomplete manuscripts cannot be accepted for editorial review.

General

- ☐ Submit original and *two* duplicate manuscripts (including three clearly separated and labeled sets of illustrations). Retain a fourth complete set as insurance against loss in the mail.
- ☐ Type manuscript double-spaced throughout (including title page, abstract, text, references, tables, and legends) on one side only on 22 × 28 cm (8½ × 11 inch) opaque bond paper with 3 cm (1¼ inch) margins all around. *This also applies to correspondence.* Type the last name of the first author in the upper right-hand corner of each page, including the title page.
- ☐ Arrange manuscript as follows: (1) title page, (2) abstract, (3) text, (4) references, (5) tables, and (6) legends. Number pages consecutively, beginning with the title page as page 1 and ending with the legend page.
- ☐ A manuscript for an *original article* ordinarily should not exceed 26 double-spaced typewritten pages, and should be proportionally shorter the more illustrations and tables that are included.
- ☐ The *text* for case reports should be *no more* than 4 double-spaced typewritten pages. If tables or illustrations are included, the text must be reduced. The text for a "how to do it" article should be even briefer, but with detailed illustrative material. Case reports and "how to do it" articles that exceed the allowable length will not be considered for publication.
- ☐ Referencing should be selective and pertain directly to the work being reported. Except in collective and current reviews, comprehensive listings serve no useful purpose and utilize valuable space. As a general guide, original articles

should have no more than 20 references; case reports, 8 references; and "how to do it" articles, 5 references.

Title Page

- ☐ Give the paper as short a title as possible. Also submit a short title of 3 or 4 words to be used as a running head. Include only the names of the authors directly affiliated with the work, stating for each the single highest academic degree. Include the name and location of no more than two institutional affiliations.
- ☐ If the paper has been or is to be presented at the annual meeting of The Society of Thoracic Surgeons, the Southern Thoracic Surgical Association, or another scientific organization, provide a footnote giving the name, location, and dates of the meeting.
- ☐ At the bottom of the page, type "Address reprint requests to Dr . . ." followed by the last name, exact postal address with zip code, *telephone number*, and *FAX number* of the author to whom communications, proofs, and requests for reprints should be sent.

Abstracts

- ☐ Provide an abstract *no longer than 175 words* for an original article. Abstracts for case reports and "how to do it" articles should be shorter (50 to 75 words). An abstract must accompany *every* contribution, except for letters to the editor. Include several (3 to 5) keywords to assist in cross-indexing the article.

Text

- ☐ Generally, the text should be organized as follows: Introduction, Material and Methods, Results, and Comment.
- ☐ *Cite references, illustrations, and tables in numerical order* in the text. (Order of mention in text determines the number given to each.)
- ☐ Spell out, or define in parentheses, all abbreviations, even if they are commonly employed.
- ☐ Give all measurements and weights in *Système International (SI) units*. See "SI Unit Implementation—the Next Step" (JAMA 1988;260:73–6).
- ☐ For statistical nomenclature and data analysis, follow the "Guidelines for Data Reporting and Nomenclature" published in *The Annals of Thoracic Surgery* (1988;46:260–1) and found in the program book for the annual meeting of The Society of Thoracic Surgeons.
- ☐ Type footnotes at the bottom of the manuscript page on which they are cited. Credit suppliers of drugs, equipment, and other material described at length in the paper in footnotes, giving company name and location.
- ☐ Type acknowledgments, including complete grant or subsidy information, at the end of the text before the references.

References

- ☐ Identify references in the text using arabic numerals in parentheses on the line. Do not cite personal communications, manuscripts in preparation, and other unpublished data in the reference list. They may be mentioned in the text in parentheses.
- ☐ Type references double-spaced on a separate sheet. *Number consecutively in the order in which they are mentioned in the text.*
- ☐ Journal references should provide *inclusive* page numbers; book references should cite *specific* page numbers.
- ☐ Double-check references for accuracy, completeness, and nonduplication.

(Continued)

- ☐ Abbreviations of journals should conform to those used in *Index Medicus*. The style and punctuation of the references should follow the formats outlined below:

Journal Article

8. Grillo HC, Suen HC, Mathisen DJ, Wain JC. Resectional management of thyroid carcinoma invading the airway. *Ann Thorac Surg* 1992;54:3–10.
(List all authors if 6 or fewer; otherwise list first 3 and add “et al.”)

Chapter in Book

12. Vouhé PR. Transplantation of thoracic organs in children. In: Fallis JC, Filler RM, Lemoine G, eds. *Pediatric thoracic surgery*. New York: Elsevier, 1991:319–29.

Book (Personal Authors or Editors)

18. Shields TW, ed. *Mediastinal surgery*. Philadelphia: Lea & Febiger, 1991:1–10.

Tables

- ☐ Tables should be typewritten *double-spaced* on separate sheets, each with a table number (arabic) and title above the table and explanatory notes and legends below. Provide a key in alphabetical order to each table to identify all abbreviations used; this key should be placed below any explanatory notes.
- ☐ Include written permission from *both the author and the publisher* to reproduce any previously published table(s).
- ☐ Tables should be self-explanatory, and the data should not be duplicated in the text or illustrations. If a table provides redundant information, it will be deleted.

Legends

- ☐ Type legends double-spaced on a single sheet. Numbers should be arabic and correspond to the order in which the illustrations occur in the text. Identify (in alphabetical order) all abbreviations appearing in the illustrations at the end of each legend. Give the type of stain and magnification power for all photomicrographs.
- ☐ Include written permission from *both the author and the publisher* to reproduce any previously published illustration(s).
- ☐ Enclose signed releases for recognizable (unmasked) photographs of human beings.

Illustrations

- ☐ Submit *triplicate* sets, each set in its own envelope, of *unmounted* and *untrimmed* black and white professionally prepared glossy prints. Components of the same illustration (eg, parts A and B) should be submitted separately. Photographs, rather than original art or photocopies, should be provided. All lettering should be done professionally and should be of adequate size to retain clarity after reduction (*final* lettering size in print should be 1.5 mm high). Illustrations will be reproduced at a width of one column (8.25 cm, 3¼ inches) or

two columns (17.15 cm, 6¾ inches), or at an intermediate width ranging from 10.16 to 12.07 cm (4 to 4¾ inches).

- ☐ Many computer-generated illustrations are unsatisfactory for reproduction and should be professionally redrawn. Roentgenogram reproductions should be no smaller than 13 × 18 cm (5 × 7 inches).
- ☐ Place the first author's last name, the figure number, and an arrow indicating the *top* on a gummed label on the back of each illustration.
- ☐ If color illustrations are to be considered for publication, submit *both* positive 35-mm transparencies and color prints. Part of the printing costs for color illustrations will be borne by *The Annals*; however, the author must be prepared to pay \$1,150 for the first color illustration on each page and \$250 for every additional color illustration on the same page.

Human Investigation

- ☐ Include the date of approval by the local institutional human research committee or the ethical guidelines that were followed by the investigators in the Material and Methods section of the manuscript.

Humane Animal Care

- ☐ The Material and Methods section must contain a statement assuring that all animals have received humane care in compliance with the “Guide for the Care and Use of Laboratory Animals” published by the National Institutes of Health (NIH Publication No. 85-23, revised 1985).

Conflict of Interest

The Annals expects authors to disclose any commercial association that might pose a conflict of interest in connection with this manuscript. All funding sources supporting the work should be acknowledged in a footnote. Institutional or corporate affiliations of the authors that might constitute a conflict should be brought to the attention of the Editor.

Scientific Responsibility Statement

Before publication of an accepted manuscript, each author will be required to certify that he or she has participated sufficiently in the work to take responsibility for a meaningful share of the content of the manuscript, and that this participation included:

- (a) conception or design of the experiment(s), or collection and analysis or interpretation of data;
- (b) drafting the manuscript or revising its intellectual content; and
- (c) approval of the final version of the manuscript to be published.

Exclusive Publication Statement

I certify that none of the material in this manuscript has been published previously, and that none of this material is currently under consideration for publication elsewhere. This includes symposia, transactions, books, articles published by invitation, and preliminary publications of any kind except an abstract of 400 words or fewer.

(Author's Signature)

Guidelines for the Submission of Electronic Manuscripts

- ☐ Please note that only the final accepted revision of a manuscript should be submitted as an electronic file. If you are planning to submit a manuscript in this format, please check box.

I. Keyboarding of Manuscripts

- 1) Our equipment can handle the following programs (any version) in their "native" format:

IBM Compatible

DisplayWrite	Q & A Write
Executive Writer	Samna
Leading Edge	Spellbinder
Microsoft Word	Volkswriter
Multimate	WordPerfect
Office Writer	WordStar
PC Write	WordStar 2000
PFS: Write	Xywrite
PFS: Professional	

Macintosh (do not use "Fast Save")

MacWrite
Microsoft Word
WordPerfect

Other word processors should be saved as ASCII files. For files saved as ASCII, consult the editorial office regarding the keyboarding of attributes such as bold, underline, superscript, subscript, etc.

- 2) All design considerations for typefaces, page layout, and artwork will be handled by the publisher after receipt of the electronic manuscript. **There is no need for the author to input special typesetting codes.**
- 3) Be especially sure to distinguish between the letters O and I and the numbers 0 and 1, respectively.
- 4) A "hard return" results from tapping the keyboard's **Enter** key. Use a hard return only to end a paragraph, or for titles, subheads, separate items on a list, etc. Rely on the word processor's word wrap ("soft return") within paragraphs, list items, etc.
- 5) Use your word processor's capabilities for the following text attributes:
- bold
 - underline and italic
 - subscript
 - superscript
 - strikeout

Text that will be italic in published form may be keyboarded italic or underlined.

- 6) Do not use your word processor's hyphenation capabilities. Do not right justify text. Use two hyphens for long dashes.

- 7) In tables, use only tabs, not spaces, to align columns.

II. Organization and Delivery of Electronic Files

- 1) Accepted manuscripts may be submitted on 3.5" or 5.25" diskettes, which must be either MS-DOS or Macintosh format. The author should retain copies of all files as backup. All diskettes must be accompanied by the *final* revision and a duplicate copy of the manuscript (including two clearly separated and labeled sets of illustrations) in full conformity with the standard Information for Authors on the preceding pages.

- 2) Diskettes should each be labeled with:

- author's name
- short title of article
- operating system
- format
- word processor used, including version number.

For example, DOS/DSDD/WordPerfect 4.2, or MAC/800K/MS Word v.3. Here, *DOS* and *Mac* indicate the operating system, *DSDD* (double-sided, double density) or *800K* indicates the diskette's physical format, and the remainder indicates the word processor used. Labels for your use are available from the Editorial Office.

- 3) If possible, it is helpful to have additional material such as tables, figure legends, and references saved as individual files—one file for each category. A file key should accompany the diskette.

- 4) Submit only the final accepted version of a manuscript. It is essential that submitted electronic files exactly match the final printout.

- 5) Diskettes should be packed between cardboard (or with foam or bubble-wrap) in an envelope that states that magnetic media is contained.

Please submit your word-processing diskette, the final revision and a duplicate copy of your manuscript, and two clearly separated and labeled sets of illustrations to:

An invitation for current subscribers

Bound Volumes of THE ANNALS OF THORACIC SURGERY

Reserve your 1992 bound volumes now! As a special service to current subscribers only, **THE ANNALS OF THORACIC SURGERY** is available in bound volumes, priced at \$90.00 (US) and \$110.00 (International). The two volumes for 1992 (Volumes 53 and 54) are bound in blue buckram—the same high quality binding you would find in a library—with stamped lettering on the spine. These handsomely bound volumes include:

- complete author and subject indexes
- editorial content only, with all advertising removed
- sturdy bindings for durable reference

From now on, when you receive your regular monthly copy of **THE ANNALS OF THORACIC SURGERY**, don't hesitate to tear out or mark up articles of particular interest. These specially bound volumes include every issue in perfect condition to help you keep your personal library complete, organized and current.

Reserve your 1992 bound volumes by returning the order form below.

Clip and mail to: Elsevier Science Publishing Co., Inc. PO Box 882, Madison Square Station, New York, NY 10159

ORDER FORM

☐ Please send me bound volumes 53 & 54 for **THE ANNALS OF THORACIC SURGERY**.* Both volumes will be shipped together for a total cost of \$90.00.

☐ Please send me bound volumes 51 & 52 for **THE ANNALS OF THORACIC SURGERY** from 1991. Both volumes for \$90.00

Outside the US, please add \$20.00 for postage and handling.

☐ Please start my annual standing order to receive bound volumes of **THE ANNALS OF THORACIC SURGERY**. Two bound volumes automatically will be shipped together at the end of each year.

Note: *Offer available only for subscribers to **THE ANNALS OF THORACIC SURGERY**. Please allow 3-5 weeks for receipt of your bound volumes.

Please return to:
Elsevier Science Publishing Co., Inc.
P.O. Box 882
Madison Square Station
New York, NY 10159

PAYMENT

Enclosed please find my: ☐ personal check ☐ bank draft

EVENTS OF INTEREST

Brief notices of meetings, courses, and symposia relevant to cardiothoracic surgery are published as a service. They should be formatted as follows: meeting title, date, place, sponsor, accreditation, director, fee, minimum/maximum attendance, and address/phone for further information. Announcements should be sent at least 4 months in advance of publication to *The Annals of Thoracic Surgery*, 3108 Queeny Tower, Barnes Hospital Plaza, St. Louis, MO 63110-1041; telephone, (314) 361-6084.

■ One Hundred Thirteenth Annual Meeting of the American Surgical Association, Baltimore, Maryland—April 1-3, 1993

For information on this meeting, contact American Surgical Association, Department of Surgery, CB 7245, University of North Carolina, 136 Burnett-Womack Building, Chapel Hill, NC 27599; or telephone (919) 966-4320 (facsimile: (919) 966-6009).

■ Thirteenth Annual Meeting of the International Society for Heart and Lung Transplantation, Boca Raton, Florida—April 1-3, 1993

For information on this meeting, contact ISHLT Headquarters, 435 Michigan Ave, Suite 1717, Chicago, IL 60611; or telephone (312) 644-0828.

■ American College of Surgeons, Montreal, Canada—April 25-28, 1993

For information on this meeting, contact American College of Surgeons, 55 E Erie St, Chicago, IL 60611; or telephone (312) 664-4050 (facsimile: (312) 440-7014).

■ Seventy-third Annual Meeting of the American Association for Thoracic Surgery, Chicago, Illinois—April 26-28, 1993

For information on this meeting, contact American Association for

Thoracic Surgery, 13 Elm St, Manchester, MA 01944; or telephone (508) 526-8330 (facsimile: (508) 526-4018).

WE'RE WIRED

ABOUT OUR

NEW TEMPORARY

PACING LEADS

Medtronic now has a new family of heartwires that deserve to be called temporary pacing leads.

The unique discrete electrode, which allows reliable pacing and sensing, is what makes our Model 6500 and our new smaller Atrial and Pediatric temporary myocardial pacing leads more than just generic heartwires. And the sutureless fixation coil, found only on Medtronic temporary pacing leads, allows faster, easier, less traumatic implant. Please contact your local Medtronic representative for more information about any of our complete line of Medtronic® Temporary Myocardial Pacing Leads.

From the company with over 40 years of pacing experience.

CAUTION: Federal law (U.S.A.) restricts this device to sale by or on the order of a physician. For detailed information on intended use, contraindications, precautions, and warnings, please refer to the Instructions For Use provided with the product.

Toll-free Physician Advisory Number: 1-800-328-2518

Medtronic 

Unsocialized Medicine: The Decline of Surgical Collegiality

William A. Cook, MD

North Andover, Massachusetts

Fellow members and guests. Let me first express my gratitude for the honor you have paid me in allowing me to be your president. It is the apex of my medical career. I also want to thank all who have contributed to making the 39th Annual Meeting of the Southern Thoracic Surgical Association a success: the Postgraduate and Program Committees, the authors, in particular Dr Baue for his wonderful presentation on multiple organ dysfunction and Dr Naef for his glimpse into our past and future, and finally the executive staff.

Election to the Presidency of an organization is thrilling in direct proportion to one's respect for the organization, and, paradoxically, humbling in equal measure. Because the Southern Thoracic Surgical Association was my first love and continuing favorite, you will realize how elated I was to be chosen. In the reflection that followed I began to wonder at the course that took me from a small mill town in north-central Wisconsin to the podium of this great organization. Ultimately the route seemed related to the end and therefore worthy of consideration, but mostly it seemed pertinent to the topic of surgical collegiality that I have chosen as the topic of this address.

This address is not designed to actuate and therefore is not an oration. Rather it is designed to promote reflection,

Presented at the Thirty-ninth Annual Meeting of the Southern Thoracic Surgical Association, Wesley Chapel, FL, Nov 5-7, 1992.

by an informal stringing together of ideas to see what happens. This is defined as an essay by Dr O. B. Hardison in his essay on the essay [1]. That is, it is a trial or test of ideas. The form is uniquely appropriate to our times. The first and greatest essayist, and author of the term, was Michel de Montaigne. He sent forth his first collection in 1580, into a world turned chaotic by the Reformation and still stunned by the ferocity of the St. Bartholomew's Day Massacre, just eight years before. He said that he sought a calmness and a detachment he called *Ataraxy* to follow an inward questioning. His motto was "What Do I Know."

One thing I know is the path I have taken. My family was my earliest influence. To paraphrase the opening lines of Norman Maclean's wonderful book *A River Runs Through It* [2], in our family there was no clear line between religion, fly fishing (Fig 1), and dentistry (Fig 2). Like Reverend Maclean, my father (Fig 3) used the word *beautiful* as a natural form of speech. It was applied equally to a well-cast fly, a perfect gold inlay, and his favorite hymns. It was a paradox in a man so tough at the core. It led my sister, my brother, and me to an early recognition of the intrinsic worth of a thing well done.

My mother (Fig 4) created in us an unquenchable curiosity about every aspect of life; about music and art, literature and nature, and people, all carried along by her own bright intellect and informed by her sense of social justice.

The physicians in my hometown could well have been selected as role models. They were caring and kindly, intelligent and involved, and they actually talked to kids. Because I was sick with histoplasmosis for a few years and had a lot of contact with them it is easy to see why I always wanted to be a doctor. Getting there was a rather undistinguished process.

My surgical training was provided by a number of outstanding surgeons, some of whom I wish to present. Doctor Fiorindo Simeone (Fig 5) was my Chief of Surgery. He quickly gave us interns to understand the responsibility of a surgeon with the observations: "When one man allows another to assail his body with stainless steel, they have established a life-long contract," and, "We have much to learn from our patients but must never forget how dearly they pay for our tuition." Coupled with his demanding sternness was a boundless intellectual bent. He once told me, in awe, that the thing that impressed him most in his career was the time Dr Edward Churchill showed him two whole file drawers full of papers he was working on. He himself introduced to surgery Lewis Carroll's concept expressed by the Red Queen that only

Fig 1. A. R. Cook with trout.

by out-distancing ourselves do we uncover new problems [3]. This image was applied to the recognition of shock-lung in Vietnam military casualties so badly injured they would have died on the field in prior wars.

In 1960 Dr Simeone arranged for me to spend a year with his old friend Prof John Kinmonth (Fig 6) at St. Thomas' Hospital in London. This remarkable man accepted a pea-green foreign resident in his newly formed cardiac surgery unit as if he were a member of the royal family and provided me with the opportunity to perform, analyze, and report my first scientific research. He also

Fig 2. A. R. Cook with drill.

Fig 3. Arthur R. Cook, DDS.

took me to the theater and for a ride in his Morgan 2+2. On my return he was so gracious and involved as to write to Dr George Clowes and suggest that thoracic surgery might be a good field for me to pursue.

There was no saying no to Dr Clowes (Fig 7), and thus I was recruited to one of the most exciting clinical research units in the country. We had the first Engstrom volume ventilator and Siggard Anderson rapid blood-gas analyzer in America, the first membrane oxygenator, and, thanks to Dr Louis Del Guercio, the first bedside cardiac output equipment. Due to Dr Clowes' insatiable scientific curiosity, patients with every conceivable disease process were studied. This experience created a physiologic underpinning for all my subsequent surgical life. When I announced that I was taking this treasure back to Wisconsin, he said "no, you're not, you're going to Montreal with me to meet Dr Webb." That is how I got my first job.

Watts Webb (Fig 8) is a consummate master of conceiving, conducting, polishing, and funding thoracic surgical research, and he gave his all to show me how. Our clinical and laboratory research covered a wide variety of sub-

Fig 7. George H. A. Clowes, MD.

jects, so much so that after presenting my first paper to this association in 1965 on some adverse effects of smoking and my next on the adverse effects of alcohol, several senior members threatened not to accept any more papers from us for fear we would find something fundamentally wrong with sex.

Finally, while in Dallas, I had the privilege of working with Dr Robert Shaw (Fig 9). His gift for perceiving the practical good that thoracic surgery can do was epitomized in a case he asked me to assist him with, in which transthoracic drainage and grafting of a Pott's abscess reversed a paraplegia of 48 days' duration. A year later I had done some other transthoracic spinal cases when he wrote from Afghanistan to offer two of his Afghani cases and the proposal that I write them all up to call attention to the procedure in the American literature.

This has been a lengthy description of what for most of my generation was a common experience. I give it to make two points. First, note the high degree of personal involvement of my mentors. They never sent me to a

meeting, they took me, and introduced me to their friends. Second is the enormous variety of clinical and research experience to which I was exposed along the way. This clinical and laboratory experience was associated with a high degree of socialization. I do not think this occurs commonly today. Those men, and others too numerous to mention, were also eager that we share their involvement with their colleagues in everyday interchange, and particularly with their organizations. Many of those men are in this room today.

Dallas was a good example. Doctors Paulson and Shaw made rounds on the wards at Parkland Hospital each Saturday morning, and this was followed by a mortality conference. Imagine, if you can, Robert Shaw, Don Paulson, Maurice Adam, Milton Davis, Hugh Wilson, Watts Webb, Hal Urschel, Bill Ashe, Paul Ellis, John Kee, Tom McSwain, and Eldon Sieble all in one room defending their clinical decisions. Talk about discussion; we should have had our own Osler Abbot award. No one had to be prompted to attend. No one would have missed it. We

had one twentieth of the 1966 membership of this association, possibly the loudest twentieth, but looking at the roster for that year I suspect that members from Nashville, Memphis, and Atlanta were sharing the experience.

Collegiality, scientific interchange, and fun all happened at once and I was thrilled to be part of it. Imagine my delight when I went with Dr Webb to Freeport to deliver the infamous smoking paper and discovered the same mix in the Southern Thoracic Surgical Association. I fell in love with this organization, and I am happy to say my love affair continues unabated after 27 years. The catalogue of brilliant scientific information, close personal friendships, riotous laughter, and unadulterated mischief provided by this organization are among my brightest memories. Sadly, this has not been everyone's experience.

During the past year I have attempted to collect some history of the organization and also the demographics of attendance at the meetings. Due to fading memories, incomplete Association records, and simple disinterest, these demographics are flawed, but, still, certain patterns emerge. The most striking and unusual is that looking at each yearly group of new members between 3 and 6 people begin to attend regularly and then never stop. The founding of The Society of Thoracic Surgeons did not affect attendance at this meeting. This is true of recent years as well as the early years. From this group have come all of your officers and committee members, and many of the finest scientific presentations. Clearly, for them the organization provided exactly the role for which it was founded.

Equally clearly, it has not done so for the greater proportion of members. More than 500 members have attended two meetings or less. It is this group with which I am concerned. After a year of contemplation the question for me remains, How did the organization fail these people or they it? Before the study was complete I had thought it was a phenomenon of the younger members, but that is not true. It was equally noted in the founder's group.

Here I should put forward the impetus for this address. I belong to many medical organizations ranging from the most general to the most specialized and local. A common disease affects many of these organizations. They are becoming senile and in some cases dying. In the time I have been in Massachusetts I have seen the demise of the Surgical Section of the Massachusetts Medical Society. It was founded before the Revolutionary War, and its history was rich with famous men and their deeds. There has been a simultaneous decrease in attendance and shift to older members in the Massachusetts Chapter of the American College of Surgeons. This was once the largest and most active chapter in the United States. Please recognize that I take what happens to my organizations personally. This decline appears not to be a phenomenon limited to medicine. Patients tell me the same thing is happening in the service organizations, the Masonic Lodge, and the Knights of Columbus. What is behind this decline in collegiality and socialization, how might it affect the Southern Thoracic Surgical Association, and what if anything can be done about it?

The historical material I solicited from the members was filled with letters, slides, articles, and lots of memories. Strangely, few if any dealt with the scientific content of the meetings. Almost all recalled the fun, the people, and the places. However, one member responded, "who cares, why dwell on the past?" This would seem an easy question to answer but in fact requires our consideration. A medical student who is on a committee with me said, "Much of the thrust of current meetings seems to be how to recapture medicine as it was. It will never again be as it was. We want to go to meetings that deal with our realities." What are those realities, and what is the process in which we find ourselves?

It should be clear from my earlier remarks what I thought medicine should be like. Now, with many of my contemporaries, I am caught in a frustrated grieving for the loss of my youthful altruism and expectations. This process has gone from early denial to anger and thence to resigned acceptance. On the way it has definitely permeated our contemporary discourse.

For one example, in 1965 we began to deal with Medicare and Medicaid and their erosion of the doctor/patient relationship. Medicaid in particular began under an evil star. It was an outgrowth of the deceptive American myth that nothing is of value if it is not expensive and has driven the cost of medical care to cosmic levels. In addition, at a single stroke it negated and demeaned a 200-year-old tradition of free medical care, of which we were justifiably proud, and effectively prevented us from giving it. Now 35 million Americans do not have medical insurance and we are blamed for it. Well, a few years ago my office medical assistant analyzed my billing costs for Medicaid patients and found they were greater than collections. So we instituted a policy of free care, which avoided billing them. The bureaucrats told us we could not do that because it undermined the system. Did I have anger and denial—you bet. Did I have acceptance—not yet.

In his presidential address to the Massachusetts Chap-

ter of the American College of Surgeons Dr Stuart Strong noted that these pressures have caused the subjects discussed at meetings to reflect anxiety and grief and to deal with the intrusion of external forces in our practices [4], and to shift organizational behavior toward economic goals. By belonging to these organizations we are tacitly drawn into this dialogue instead of maintaining an individual ethicism in which the patient and his or her care are our primary consideration. Young surgeons, saddled with enormous debt at the end of training, feel these same pressures even more strongly than we do, and for many this is a source of embarrassment. Clearly they do not want to belong to an organization that underlines the least altruistic areas of their life.

Well, the good news is that the entire 1992 meeting of the Massachusetts Chapter was spent on laparoscopic surgery with no discussion of any politically centered issues. We had the largest attendance and youngest group in nearly a decade. In a letter to the Editor of the *Journal of the American Medical Association*, Dr Bernstein of the Boston University School of Medicine notes that a study of their graduates from 1986 to 1990 showed no association between debt and choice of a highly paid specialty and that this corroborated the Graduate Questionnaire of the Association of American Medical Colleges [5]. Doctor Strong went on to reflect that we could not assume that our medical mentors were totally happy with their choice and experience of medicine. Yet they usually exuded pleasure, interest, and energy in its practice, and close personal contact with their trainees.

Earlier this year Dr Waldhausen, reflecting on the history of the American Association for Thoracic Surgery and the Snowbird Conference on Cardio-Thoracic Surgical Training, brought home some of these factors with great force [6]. He said, "For an association to remain viable and to fulfill its purpose, its members must not look only on the glorious past. They, and particularly the younger generation, must look to the future and at the challenges that face us." He noted further that "We must face the fact that our specialty in many regards has been shrinking; that thoracic surgeons introduced cardiac catheterization, pediatric cardiac surgery, critical care units, and support for cardiogenic shock and that in these and many other areas we have retreated completely, and in others are hardly visible." He states, "We have, in part, lost our way. We no longer participate in total care of our patients. Too often we have become OR technicians and are forcing our residents into a similar mold." Possibly this is a mold they do not want and of which they cannot be proud.

Doctor Anderson, in his presidential address to the Western Thoracic Surgical Association, also enumerated the many changes in thoracic and cardiovascular surgery and pointed out how interrelated they were with broader social changes [7]. Certainly our younger members have been subject to all these medical and societal pressures. You may have noticed that the winds of change seem to be piping up.

I believe we are not only in a period of gradual change. We are in a period of upheaval. We are not only the

passive victims of change. We ourselves are fomenting it. The recent Presidential election makes that manifestly clear. This societal upheaval spreads across every facet of contemporary life. In a recent issue of his column "This View of Life" Stephen Jay Gould reflects on the parallels between his theory of punctuated equilibrium in evolutionary biology and the observations of columnist David Warsh [8]. Mr Warsh was commenting on theories of punctuated equilibrium in social science put forth by Karl Marx. Having just been to Russia and experienced the chaos that has accompanied the fall of communism, Dr Gould states that "Russia is presently in the midst of a punctuation that must soon resolve itself one way or another into some form of promise or prosperity, or some species of chaos and dissolution." He further notes Mr Warsh's argument that gradualism is being challenged across a broad range of human activity: the introduction of quantum theory in physics, Thomas Kuhn's punctuational theory of the history of scientific ideas, and chaos theory in mathematics.

He then states that modern punctualism emphasizes contingency. This may provoke more anxiety due to its unpredictable outcome, but embodies more hope in the power of people to control their future. He concludes, "You can't think much about future stabilities when you must struggle to put food on the table." That struggle is best buoyed by a good sense of humor such as that seen in the current version of Russian nesting dolls. A big Yeltsin is on the outside and inside, first Gorbachev then Brezhnev, Khrushchev, and Stalin, and finally a tiny Lenin at the core.

In a recent article dealing with contemporary American intellectual life and entitled "The Cultural Wars," the philosopher Daniel Bell takes note of the "rancorous cultural war . . . over the questions of multiculturalism, political correctness, the canon and deconstructionism" taking place in American universities [9]. This has raged most publicly in the controversy over core curricula in the humanities and spilled over recently in the press. The *New York Times* for October 10th noted that the classics reading list at Columbia was being changed for the first time since the beginning of the century. The product of 3,000 years of Western thought is being casually dismissed as the politically incorrect product of DWEMs—Dead White European Males. Bell further notes that "there is no broad intellectual life and no broad intellectual public today," and that "specialization has led to an intellectual parochialism that ignores all cultural considerations outside its own narrow sphere."

Looking at the future he sees "the persistent problems of poverty and racial tension, . . . the unraveling of the middle class, . . . the erosion of its comfortable expectations," and "the possibility that this may be the first generation in American history that will leave its children poorer than itself." Added to that bleak picture he notes the loss of a cohesive utopian, universalist philosophy present since the age of enlightenment. This has been replaced in the West by a cultural nihilism and outside the West by a resurgence of Islamic fundamentalism that challenges all the values of the West.

He concludes, "All these create different sounds and furies and different kinds of cultural wars. We may be at the end of old ideologies and old history, but there are no unified sets of beliefs to take their place, only the splintering of cultures and political fragmentation."

These combined confusions of basic cultural tenets, modern American life, American medical politics, and thoracic surgical training are the heritage we give our younger members. Is it any wonder they are not particularly interested in further political discussions and deeply enjoy the structured peace of the operating room? Is it any wonder they question the relevance of the organizations so dear to us older members?

I believe there are answers to these confusions and would note that after every historical period of great turmoil there has been a giant leap forward in the basic human condition. We are in such a period now and must do all we can to bring our profession, our specialty, our organizations, and our young members to that brighter day.

What are our resources? Let us share a little folk wisdom with Gladys Knight and the Pips [10]. First she says, "Everybody's talking about the good old days, the good old days, the good old days. Well, let's talk about the good old days. Come to think of it, as bad as we think they are these will become the good old days for our children."* Then she sings, "for it's the laughter we will remember, as long as we remember the way we were."† She could certainly have been singing about the Southern Thoracic Surgical Association or, equally, the Russian nesting dolls. Laughter has always been an essential part of our organization, and we should be careful to nurture it. People in this room have recalled the laughter of 40 years ago. It is the music of the soul.

As noted before, we are embattled on many fronts. In seeking stability we might consider the embattled little Ukrainian village of Anatevka and the family of Tevye the dairy-man [11]. He says, "In our little village everyone of us is a fiddler on the roof trying to scratch out a pleasant, simple tune without breaking his neck . . . And how do we keep our balance . . . Tradition! Because of our tradition everyone here knows who he is and what God expects him to do . . . Without our tradition our life would be as shaky as a fiddler on the roof."‡ Tradition? Have we got tradition! Thirty-three years of recognizing pompous discussion with the Osler Abbot Award. Twenty-nine years of slide perfection ensured by the scourge of the Tiki Award. Do we have golf? We have Jim Brooks, who is reputed to have invented the game. Do we have history? We have Hawley Siler, whose first historical notes were impressed with a stylus on a block of clay

dredged up from Tampa Bay, back when a good cigar was a smoke. Yes, we have tradition.

But most important, we have mentors. I should know. I have been mentored by half the men in this room; encouraged, advised, befriended, criticized, restrained, promoted, and complimented. That, I have come to believe, is our greatest intrinsic strength. We know how to advocate for a younger surgeon, and all we need is just to do it! Here is the answer to "why look back?" Because in looking back we discover the richness of our history, the stability of our traditions, the value of our laughter, and the power of mentorship to lead our young members into the next 40 years. Looking at the bright new faces among us I see the opportunity to show them the pleasures of collegiality.

Another, unstated, question was "why participate?" That answer was provided by Theodore Roosevelt. He said, "Every man owes a part of his time and money to the business or industry in which he is engaged. No man has a moral right to withhold his support from an organization that is striving to improve conditions within his sphere."

Let me return momentarily to Stephen Gould. In a discussion of the conflict between moderns and classicists he recalls Jonathan Swift's satire of 1704 [12]. This was entitled *A Full and True Account of the Battle Fought Last Friday Between the Ancient and the Modern Books in St. James's Library*. The actual battle is introduced by a dispute between a spider (the moderns) and a bee (the ancients). Pointing to his web, the spider notes its mathematical purity and originality and accuses the bee of being able to create nothing new but only to forage among the ancient flowers. The bee responds, "I borrow but cause no harm in so doing, and I transmute what I borrow into new objects of great beauty and utility—honey and wax. But you, while claiming to build only from your own innards, must still destroy a hecatomb of flies for the raw material. Moreover, your vaunted web is weak, temporary, and ephemeral, whatever its supposed mathematical beauty (while the distillation of ancient knowledge endures forever) . . . How can you claim virtue for a product . . . based on your own gall?" The answer to this debate Gould suggests lies in an epigram of Edmund Burke: "All government—indeed, every human benefit and enjoyment, every virtue and every prudent act—is founded on compromise and barter." Professor Gould notes further "if we cannot talk we cannot bargain, compromise, and understand," and sadly notes that "I can no longer cite the most common lines from Shakespeare or the Bible in class and hold any hope of majority recognition. I am troubled that the primary lingua franca of shared culture may now be rock music of the last decade." He concludes with the words of the bee, "Whatever we have got, has been by infinite labor, and search, and ranging through every corner of nature: the difference is, that instead of dirt and poison, we have rather chosen to fill our hives with honey and wax, thus furnishing mankind with the two noblest of things, which are sweetness and light." So may it be with thoracic surgery and our part in it.

On my office wall there is a picture that I have come to

* Written for Gladys Knight and the Pips by Corky Guercio. Reprinted by permission.

see as a perfect allegory for thoracic surgery today. It is a print of Winslow Homer's painting "Eight Bells." In the foreground are two mariners taking a noon-sight to fix their position by celestial navigation. A brassy light reflects from their wet oilskins as a pale sun just breaks through a storm-wracked sky. Around the ship is a tempestuous running sea. Beside them are the sturdy shrouds of a well-found sailing ship. Each man has a sextant. One is shooting the sun. The other is reading his instrument. They will compare readings for accuracy. Probably one is the captain and the other a young man learning his craft.

What is striking is that there, in the midst of the storm, these two hard-case sailors are performing a technical task that requires great skill and upon which the safety of their ship depends. By their attention to the work at hand they have created an island of calm totally detached from the forces around them. They cannot escape the sea and its storms; it is their life. But, confident of their ability and their ship, they are secure.

How closely this parallels the young surgeon and his or her mentor at the operating table, calmly performing a highly precise act despite the storm of disease and confusion in their patient, their specialty, and their world. What is being passed along is confidence and calmness in the face of adversity, what Michel Montaigne called *Ataraxy* and Sir William Osler called *Equinimitas*. When that mentorship is appropriately given and received a bond is formed that neither will wish to break. This is equally true in a surgical association.

As I look across this sea of faces, I recognize many grizzled captains of our craft and also the bright young apprentices eager to assume their roles. I am certain we have the traditions, good will, humor, ability, and confidence to pilot the Southern Thoracic Surgical Association through all the storms ahead.

Measurement of Total DNA to Assess Lung Cancers

Raymond L. Teplitz, MD, and William G. Hammond, MD

Department of Pathology and Division of Cardiothoracic Surgery, University of California at Davis School of Medicine, Sacramento, California

Can DNA ploidy alone be used to discriminate between metastases and second primary neoplasms?

Ichinose and associates [1] suggest that difference in DNA ploidy as measured by flow cytometry can be used as a criterion by which to distinguish between second primary lung adenosquamous carcinomas and metastases from a primary neoplasm. This contention is an example of a general problem, and therefore it deserves close scrutiny.

By their own criteria, Ichinose and associates state that primary adenosquamous carcinoma of the lung occurs at a low frequency (2%). Because this is such an uncommon tumor, on statistical grounds alone, one must question the frequency with which a *second* primary adenosquamous cancer of the lung could be expected to occur. This consideration alone may make the results of their study questionable.

The weakness of flow cytometry as a method for detecting low-frequency aneuploid clones was not addressed by Ichinose and associates. In alleged second primary tumors, in which the ploidy of the second clone appears to differ from the ploidy in the initial primary tumor, it is possible that the second clone was present in

as quantifiable deviations in DNA ploidy. In such instances, it is entirely possible that the new metastasizing clones might have altered ploidy; ie, a primary tumor, itself diploid, may have given rise to aneuploid and hyperploid metastases. To judge the second (metastatic) tumor as a second primary tumor on the basis of ploidy alone would be of serious conceptual question.

Cytometric estimates of DNA ploidy determine only the total quantity of cellular DNA, and not the presence of specific chromosomes. Thus, cells from a patient who has ordinary chronic granulocytic leukemia with the Philadelphia chromosome (Ph') translocation would be measured as diploid, whereas cells from the same patient in blast crisis (in which additional chromosomal changes may have been acquired) would be measured as aneuploid by flow cytometry, although they retained the specific Ph' defect that indicates the origin of the disease. Because DNA ploidy studies by flow cytometry are incapable of detecting chromosomal rearrangements, by the criteria of Ichinose and associates such a patient would be considered as having two diseases when, in fact, there were two phases of a single disease.

A technical concern about the application of flow cytometry to tumor analysis has previously been discussed by us [5]. Flow cytometry is susceptible to loss of fragile cells or nuclei because of the need to prepare suspensions by enzymatic or mechanical methods. Thus, many poorly nourished and partially degenerated tumor cell nuclei may be lost during suspension preparation, and surface sampling of archival tumor specimen blocks for flow studies often miss areas that are deep to the surface. Ichinose and associates sampled the surfaces and *selected* well-preserved areas, and thereby they introduced the possibility of real bias. The less well-preserved areas that were not sampled may have contained the less well-differentiated but mitotically more active parts of the tumor.

An additional problem was not considered. When paraffin blocks are employed as a source of material for flow cytometry, only the nuclei are measured for ploidy. The proportions of nuclei that are from tumor cells, as compared with those that are from normal tissue, are not quantitatively assessed. As tumor cells are usually larger than their normal counterparts (especially well-differentiated squamous components, but others as well), the apparent area of each cell will be large, as will its nucleus. However, when *nuclear* counts of tumor cells are done, their *number* may be quite small compared with normal components. In fact, aneuploid tumor cell nuclei may

See also page 593.

the initial primary tumor but of low frequency. It is a shortcoming of flow cytometry that low-frequency events are missed. Indeed, recent reviews [2, 3] have noted that about 20% of flow cytometric specimens claiming to show diploidy actually contain one or more aneuploid clones when the material is appropriately studied.

The biological likelihood of developing, in the primary neoplasm, additional clones the ploidy of which differs from that initially present was not fully assessed. The contemporary view of carcinogenesis involves sequential mutations; for example, in colorectal carcinogenesis, five or more mutations have been detected [4]. Several oncogene and tumor suppressor gene mutations have been associated with squamous, adenocarcinoma, and small cell carcinoma of the lung; this is doubtless true for the adenosquamous variety also. In many instances, progress through the sequence of tumor evolution—particularly metastasis—is very likely to be accompanied by significant genetic events associated with mutational and chromosomal changes [4]. These changes may be manifested

Address reprint requests to Dr Teplitz, UC Davis Medical Center, 2315 Stockton Blvd, Sacramento, CA 95817.

represent such a low proportion of the total nuclei extracted from a particular section (especially where there is heavy lymphocytic infiltration) that they may be represented in the flow histogram as an inconsequential fluctuation. If the photomicrographic illustrations in the article by Ichinose and associates are representative of the material used for nuclear extraction and subsequent flow cytometry, normal cell nuclei substantially outnumbered tumor nuclei.

Finally, there is the problem of identifying ploidy levels in cancers of the lung. For estimating ploidy level of nuclei extracted from paraffin-embedded lung cancers, Ichinose and associates used a method that only *assumes* that the dominant left-hand peak represents the G_0G_1 population and is therefore diploid; *no control cells known to be diploid* were introduced into the specimen during the flow analysis. Several ways of correcting this deficit have been reported, but none was adopted for this study. This flaw is likely to be the source of the variation among results in the various reported studies of lung cancer ploidy.

Earlier studies of lung cancer ploidy, done by DNA analysis of individual cells that were each reliably identified as being cancer cells, emphasized the frequency of hyperploidy and aneuploidy [6-8]; other studies, done by flow cytometry, have reported a higher frequency of diploid neoplasms. Some of these differences are surely due to differences in method (statistical or otherwise), but most are likely related to one or more of the various considerations noted above.

In summary, DNA ploidy differences between tumors from different sites cannot be accepted as evidence for lack of relation between the tumors until the following questions are addressed:

1. If the first tumor is a rare event, what is the probability that a second tumor of similar type is related (or unrelated) to the first?

2. Because tumor progression is associated with sequential mutations, and often with chromosomal changes, are DNA ploidy changes expected between a primary cancer and the development of its metastases?
3. Is flow cytometry the best method for assessing DNA ploidy from paraffin-embedded tumor specimens? Should the method be used for assessing rare events?

At this time, we believe that DNA ploidy alone is not an adequately specific marker for distinguishing between two primary lesions or between a primary and a metastatic lesion.

Evolving Applications of the Maze Procedure for Atrial Fibrillation

James L. Cox, MD

Division of Cardiothoracic Surgery, Department of Surgery, Washington University School of Medicine, St. Louis, Missouri

In this issue of *The Annals*, two groups of surgeons present their experiences with performing a surgical procedure designed specifically to ablate atrial fibrillation in conjunction with the repair of other cardiac abnormalities. Bonchek and associates [1] report the application of the maze procedure for paroxysmal (intermittent) atrial fibrillation in a 52-year-old patient who required closure of an atrial septal defect (ASD). They present an eloquent case for the concept of *routinely* adding the maze procedure in patients over the age of 40 years who require ASD closure, their argument being based on the fact that atrial fibrillation and its attendant detrimental sequelae will eventually develop in the majority of such patients. Hioki and associates [2] describe the use of a *modified* maze procedure in conjunction with mitral valve replacement in a 54-year-old patient with mitral stenosis and chronic (continuous) atrial fibrillation.

Although these two excellent reports would appear to share the common theme of promoting the treatment of atrial fibrillation at the same time that other cardiac abnormalities are corrected, the articles actually are quite different in terms of the connotations of the individual cases. Most patients who require closure of an ASD, regardless of age, do not have preoperative atrial fibrillation. In Bonchek's case, the patient apparently did have paroxysmal atrial fibrillation preoperatively and, there-

management strategy would represent the first application of the maze procedure as a prophylactic surgical therapy for atrial fibrillation. Although the maze procedure has proved to be quite promising as a *therapeutic* modality, I am skeptical that our cardiologic colleagues are yet prepared to accept it as a *prophylactic* procedure. This unfortunate but realistic concern, however, does not sway the logic of the recommendations proposed by Bonchek and his associates.

It is extremely important for the reader to understand that the surgical procedure performed by Hioki and associates is *not* the maze procedure. The original description of the maze procedure [3] (Fig 1), as well as the two subsequent modifications that we have made (Figs 2, 3), includes an incision that *completely encircles the orifices of the pulmonary veins*, thereby isolating them from the rest of the heart. Rather than isolating the pulmonary veins with such an encircling incision, Hioki and associates extended the short posterior vertical atriotomy from the mitral valve straight up the posterior wall of the left atrium *between the right and left pulmonary veins* (Fig 4).

We performed this exact procedure on March 8, 1990, in a 50-year-old woman with severe mitral regurgitation and chronic atrial fibrillation. The reason for our placing the single incision *between* the pulmonary veins rather than *around* them was that it had taken us 1 hour of aortic cross-clamp time to repair the mitral valve and, being early in our experience with the maze procedure, we did not feel comfortable in subjecting the patient to the extra cross-clamp time required to perform the encircling incision. As a result, we compromised by placing the incision between the pulmonary veins, a compromise that required substantially less time to perform. The patient had no further atrial fibrillation until approximately 6 months postoperatively when chronic atrial fibrillation again developed, which has continued for the past 2 years.

This unhappy experience taught us two important lessons: (1) any major modification of the incisions used for the maze procedure should be thoroughly tested in the research laboratory before clinical application and (2) the concept upon which the true maze procedure is based is an accurate one. In other words, what better control could one have to demonstrate the efficacy of the maze procedure than an operation almost identical to it that does not work?

Although Hioki's patient has remained free of atrial fibrillation for at least 1 year postoperatively, our experience would indicate that this modification of the maze procedure will not yield results comparable with the true

See also pages 607 and 776.

fore, could be expected to continue to have this arrhythmia postoperatively. Thus, a strong argument can be made for doing something at the time of the ASD closure to preclude the long-term problems associated with postoperative atrial fibrillation in this particular patient. However, the most important connotation of Bonchek's article was that a similar argument could be made for performing the maze procedure in *all* patients over the age of 40 years who require ASD closure even if they do *not* have preoperative atrial fibrillation. This recommendation is based on the available literature, which clearly documents the fact that atrial fibrillation will eventually develop in 50% of patients in this age group who undergo ASD closure. Based on the comprehensive review of the available data by Bonchek and associates, I would concur with their recommendation. However, it is worth noting that such a

Fig 1. Original maze procedure: This is a schematic depiction of the atria viewed from posteriorly (below) with the corresponding anterior portion of the atria flipped up and depicted above. Note that the orifices of the pulmonary veins are completely encircled and, therefore, are isolated from the rest of the heart.

maze procedure and, therefore, should not be recommended. We believe this modification fails for two reasons: (1) too much contiguous atrial myocardium remains between the right pulmonary veins and the inferior vena cava postoperatively, allowing a macroreentrant circuit to develop around the orifices of these structures (Fig 5) and (2) the orifices of the right upper and right lower pulmonary veins can serve as conduction obstacles around which a smaller macroreentrant circuit can develop (Fig 6).

Despite our concern about the "cardiological correctness" of performing the maze procedure as a prophylactic

Fig 2. First modification of the maze procedure: Same view as in Figure 1. Again, note that all orifices of the pulmonary veins are isolated from the rest of the heart.

measure and our belief that the modification of the maze procedure described by Hioki and associates is likely to fail in a substantial number of patients, both of these groups should be commended for expanding the applications of the maze procedure into other areas of cardiac disease in an effort to improve the ultimate outcome of surgical intervention. Such intellectual probing into established clinical practices represents the cornerstone of our specialty, and it is only through such endeavors that our patients may realize the full benefit of the more standard corrective procedures.

Fig 4. Same view as in Figure 1. These are the incisions described in the article by Hioki and associates [2] and first performed by us in 1990 in an unsuccessful attempt to cure atrial fibrillation in a patient undergoing concomitant mitral valve repair (see text for further discussion). Note that the pulmonary vein orifices are not isolated from the rest of the heart.

When Does One Replace the Heart in Ischemic Cardiomyopathy?

Irving L. Kron, MD

Department of Surgery, University of Virginia Health Sciences Center, Charlottesville, Virginia

Cardiac transplantation is a means of providing near-normal cardiac function in patients with end-stage cardiomyopathy. One-year survival is in the range of 80% to 90%, and 5-year survival is around 65% [1]. The major problem with transplantation is lack of adequate donor supply [2]. On our own service, the yearly attrition on our waiting list for heart transplantation is between 10% and 20%. This is similar to most other transplant centers.

In patients with idiopathic cardiomyopathy, there really is no surgical option other than transplantation. There is an option, however, in patients with ischemic cardiomyopathy. Luciani and colleagues [3] have attempted to analyze how patients will do who have standard coronary revascularization and compare this group with those who undergo heart transplantation or medical therapy. They studied 143 patients with ischemic cardiomyopathy, as defined by left ventricular ejection fractions less than 0.30. The medically treated patients fared the worst, with an actuarial 5-year survival of 28%. The patients undergoing coronary revascularization had a relatively high perioper-

ative angina connotes viable myocardium. We noted that although angina was a predictor of a good result, lack of angina did not predict a poor result. We have attempted to use thallium 201 scintigraphy to predict viable myocardium with mixed results. In our hands, the improvement in ventricular function clearly does not equal that of transplantation. The mean increase in ejection fraction in our patients was 8%. Despite this, the majority attained New York Heart Association class I status.

Coronary revascularization should be the first-line therapy for patients with ischemic cardiomyopathy if there are good distal vessels and a probability of viable myocardium. Clearly, there are just not enough hearts available for transplantation, and the long-term results of revascularization are quite good. If a patient fails revascularization and has persistent heart failure, then transplantation is still an option. A previous coronary bypass graft does not increase the risk of transplantation [5]. There are two clinical questions related to ischemic cardiomyopathy that have not yet been answered. The first question is how to accurately predict that coronary revascularization will be successful. Clearly, the concept of "hibernating myocardium" has to be better diagnosed and defined. The second question is how to predict and prevent late sudden death after coronary artery bypass grafting in this group of patients. Seven of eight late deaths in our series were due to arrhythmias. We are now participating with other centers in the coronary artery bypass grafting-patch (CABG-Patch) trial. This trial consists of randomizing patients who are to undergo coronary artery bypass grafting and have reduced ventricular function to placement of the automatic implantable cardioverter defibrillator. Hopefully, this study will determine if the automatic implantable cardioverter defibrillator does indeed prolong survival after coronary revascularization in patients with ventricular dysfunction.

See also page 719.

ative mortality of 20%, but the actuarial survival for this group at 5 years was 80%. Operative mortality for transplantation was 11.6%, and the actuarial five-year survival was 82% at 5 years. Nineteen patients died waiting for heart transplantation during the study period. Luciani and associates demonstrated that coronary revascularization could certainly be done successfully even in patients with markedly reduced ventricular function. They also noted that medical therapy offered extremely poor results in patients with depressed left ventricular function related to coronary disease.

Although some of the differences in outcome may certainly have been due to patient selection, I agree wholeheartedly with their conclusions. My colleagues and I [4] have previously described 39 patients with preoperative ejection fractions of less than 0.20 who underwent coronary artery bypass grafting. The mean left ventricular ejection fraction in our group of patients was 0.18. There was one operative death (2.6%), and the 3-year survival rate was 83%. Most patients did well, although 3 continued to have severe heart failure; 2 of these 3 underwent successful cardiac transplantation.

There is no doubt that certain patients with severe ischemic ventricular dysfunction will do well with coronary revascularization. The difficulty is in predicting which ones. Luciani and associates suggest that preoper-

Third-Time Coronary Artery Bypass Grafting: Midterm Results

Walter H. Merrill, MD, C. Craig Elkins, MD, James R. Stewart, MD, William H. Frist, MD, and Harvey W. Bender, Jr, MD

Department of Cardiac and Thoracic Surgery, Vanderbilt University School of Medicine, Nashville, Tennessee

Minimal data are available regarding the results of patients who have undergone myocardial revascularization more than twice. The records of 13 consecutive patients who underwent a coronary artery bypass procedure for the third time were reviewed. The indication for operation was unstable angina in all patients. All patients were placed on cardiopulmonary bypass through a median sternotomy. The mean number of bypass grafts placed at the third operation was 1.9 (range, 1 to 3 grafts). A new internal mammary artery graft was placed in 6 patients (2 had prior internal mammary artery grafts). Hospital mortality was 7.7% (1/13). The single death was due to incomplete revascularization in a patient with

poor distal vessels. Three patients required intraaortic balloon pump support postoperatively, and 2 patients had prolonged ventilatory insufficiency. There have been no late deaths. The 12 survivors have been followed up a mean of 44 months (range, 6 to 90 months). Four remain asymptomatic; 5 have mild angina easily controlled with medication. All except 1 are in improved condition compared with their preoperative status. We conclude that a third myocardial revascularization can be performed with low mortality and morbidity and with the expectation of long-lasting symptomatic improvement.

(*Ann Thorac Surg* 1993;55:582-5)

The efficacy of coronary artery bypass grafting for patients with symptomatic myocardial ischemia is well established in the literature. During the last 10 years multiple reports have documented excellent results after repeat coronary artery revascularization. Reoperative coronary artery bypass operations are increasing in frequency. It is estimated that approximately 18% of coronary artery revascularization cases are reoperative procedures. Lytle and associates [1] documented survival rates of 90% at 5 years and 75% at 10 years after coronary artery reoperation in 1,500 patients. According to Cosgrove and associates [2], as the population at risk for coronary artery disease ages and increases in size the number of reoperative procedures may increase exponentially. Consequently, an ever-increasing pool of patients now is being seen with need of coronary revascularization for the third time.

The Vanderbilt University Medical Center experience with patients who have undergone a third coronary artery bypass procedure has been reviewed to assess patient characteristics, to determine hospital mortality and morbidity, and to evaluate quality of life after operation.

Patients and Methods

The records of all patients who underwent coronary artery bypass grafting at this center during the period April 1, 1985, to April 30, 1992, were reviewed. At Vanderbilt University Hospital and the Nashville Veter-

ans Administration Hospital a total of 2,117 coronary artery bypass procedures were performed. There were 1,830 primary operations (86%) and 287 reoperative procedures (14%). Thirteen patients (0.6%) underwent coronary artery revascularization for the third time. There were 12 men and 1 woman with a mean age of 57 years (range, 46 to 69 years). Their average age at the first operation was 46 years (range, 38 to 57 years), and their average age at the second operation was 51 years (range, 41 to 62 years). The average interval between their first and second operations was 5.7 years, and the average interval between their second and third operations was 5.5 years.

The indication for the third revascularization in all 13 patients was unstable angina that was refractory to medical management. Smoking and hypercholesterolemia were the two most common of the classic risk factors of coronary artery disease present in these patients. Other risk factors included hypertension, hypertriglyceridemia, family history, obesity, and diabetes. All patients underwent preoperative cardiac catheterization to delineate native coronary artery and bypass graft anatomy and to assess left ventricular function. Left ventricular ejection fraction and end-diastolic pressure were measured during catheterization. In some patients left ventricular function was also assessed by surface echocardiography or radionuclide ventriculography.

All operative procedures were performed through a median sternotomy. Cardiopulmonary bypass with mild systemic hypothermia (22° to 28°C) was used with insertion of the arterial perfusion cannula in the ascending aorta in 7 patients and in the femoral artery in 6 patients. The femoral artery and vein were not routinely exposed,

Presented at the Thirty-ninth Annual Meeting of the Southern Thoracic Surgical Association, Wesley Chapel, FL, Nov 5-7, 1992.

Address reprint requests to Dr Merrill, The Vanderbilt Clinic, Room 2986, Nashville, TN 37232-5734.

and the arterial perfusion cannula was inserted in the femoral artery only when a site for cannulation was not available on the ascending aorta. The mean aortic cross-clamp time was 41 minutes (range, 21 to 77 minutes), and the mean pump time was 124 minutes (range, 55 to 233 minutes). Myocardial protection was achieved with antegrade cold (4°C) crystalloid cardioplegia infused through the aortic root. An intraaortic balloon pump was placed intraoperatively in 3 of 13 patients to assist in weaning from cardiopulmonary bypass.

None of these 13 patients had the internal mammary artery (IMA) used as a bypass conduit at their first operation, whereas 2 patients had three IMAs used during their second procedure. At their third revascularization 6 patients had seven IMAs used as bypass conduits. Of the 13 patients, 8 had IMA grafts used during at least one of their three operations.

Revascularization was considered complete only if all major regions of myocardium in the distribution of the right, left anterior descending, and circumflex coronary artery systems were supplied by either: (1) a native coronary artery free of hemodynamically significant narrowing, (2) a previously inserted graft free of hemodynamically significant narrowing, or (3) a new graft inserted at the third operation. Complete revascularization was performed in all but 1 patient, in whom it was impossible to place a graft to the left anterior descending coronary artery secondary to severe diffuse distal disease. Reverse saphenous vein (greater and lesser) and IMA grafts were employed in all patients. The average number of grafts was 2.8 at the first, 2.4 at the second, and 1.9 at the third operation. During the third procedure 10 patients had their left anterior descending system, diagonal system, or both revascularized; 9 had grafts to their circumflex (obtuse marginal) system; and 4 had grafts to their right coronary system.

Results

All patients survived the operation, but there was one hospital death (mortality rate, 1/13 [7.7%]). The death occurred on postoperative day 3 in the single patient who could not be completely revascularized. Autopsy documented the cause of death to be myocardial ischemia and multiple pulmonary emboli.

Eight patients were discharged from the hospital without complication after an average postoperative stay of 8.1 days. One patient sustained a perioperative subendocardial myocardial infarction manifested by ischemic changes on a postoperative electrocardiogram and an elevated level of creatine kinase isoenzyme (MB band > 5%). This patient was discharged without further sequelae on postoperative day 9. One patient was febrile, and blood cultures documented a gram-negative bacteremia. No source of the bacteremia was identified, and after appropriate antibiotic therapy the patient was discharged 12 days after operation. Two patients had a prolonged intensive care unit stay secondary to sepsis and respiratory failure. These 2 patients remained on mechanical ventilatory support for 27 and 46 days, respectively, and 1 required a tracheostomy.

The average preoperative ejection fraction was 0.47 (range, 0.25 to 0.65), and the average left ventricular end-diastolic pressure was 19.5 mm Hg (range, 8 to 26 mm Hg). Those patients discharged without complication had an average ejection fraction of 0.42 (range, 0.25 to 0.65), whereas patients with complications had an average ejection fraction of 0.56 (range, 0.50 to 0.65). The mean left ventricular end-diastolic pressure was 19 mm Hg (range, 8 to 26 mm Hg) in patients without complications and 20 mm Hg (range, 12 to 26 mm Hg) in the patients with complications. If the 2 patients with respiratory failure are excluded the patients were extubated an average of 1.2 days (range, 1 to 2 days) after operation, and they were transferred to a regular floor after an average stay of 3.9 days (range, 2 to 6 days) in an intensive care or step-down unit. The average postoperative hospital stay for all 12 surviving patients was 15.7 days (range, 6 to 57 days). If the 2 patients with respiratory failure are excluded the average postoperative hospital stay was 8.6 days (range, 6 to 12 days).

Three of the thirteen patients (23%) required an intraaortic balloon pump postoperatively. All intraaortic balloon pumps were inserted in the operating room just before weaning from cardiopulmonary bypass. Two patients had the intraaortic balloon pump removed on postoperative day 2, and 1 had it removed on postoperative day 7. Two patients with respiratory failure required inotropic support for 10 and 15 days, respectively. The other patients required no more than 2 days of inotropic support. Three patients remained on a regimen of intravenous antiarrhythmics for longer than 2 days.

No concomitant procedures were performed in these patients. One of the 13 patients required reoperation for bleeding.

There were no wound infections, and no patient experienced a transmural myocardial infarction.

All of the patients have been followed up for a mean of 44 months (range, 6 to 90 months). There have been no late deaths. Four patients have had a documented myocardial infarction at an average of 40.5 months postoperatively. Four patients are free of pain, and 5 have mild exertional angina. One patient has moderate angina at 40 months postoperatively, and 1 has severe angina with congestive heart failure 77 months after operation. One patient had a subxiphoid incisional hernia repaired 11 months postoperatively. There have been no other late complications.

Comment

Reoperative coronary artery bypass procedures are becoming more common, and they constitute nearly one fifth of all coronary artery bypass operations [3]. It is anticipated that the number of multiple reoperative revascularization procedures will continue to increase. Several series have documented overall excellent results in patients undergoing myocardial revascularization for the third time [4-7]. Young age, absence of IMA bypass, incomplete revascularization, New York Heart Association class III or IV, and single-vessel or double-vessel disease were found to be the most important predictors of

repeat coronary artery bypass procedures by Cosgrove and associates [2]. In patients undergoing third-time coronary revascularization, Blakeman and colleagues [5] and Brenowitz and co-workers [4] found that mean age at the first operation was 49.8 and 48.0 years, respectively. These ages are similar to the age at first coronary artery bypass in our group (45.8 years). None of our patients had an IMA graft at their first operation, and most of them experienced unstable angina. Only 4 patients in our group had single-vessel or double-vessel disease at the time of their first bypass procedure.

Lytle and associates [1] demonstrated that left main stenosis, New York Heart Association class III or IV, advanced age, and incomplete revascularization were predictors of in-hospital mortality after redo coronary artery bypass. The single death in this series occurred in a patient who was 46 years of age and had unstable angina and severe left main coronary artery disease. The cause of death was myocardial ischemia due to incomplete revascularization because of severe diffuse distal vessel disease. Brenowitz and co-workers [4] and Cosgrove and associates [2] have reported impaired left ventricular function as a predictor of poor outcome in reoperative coronary revascularization. Five of 13 patients in our series had an ejection fraction of 0.40 or less, and none experienced postoperative morbidity or mortality.

During the period covered by this study 8 patients with profound left ventricular dysfunction were evaluated for persistent angina or congestive heart failure after a second coronary artery bypass procedure. Rather than proceed with an attempt at a third myocardial revascularization these patients all underwent orthotopic cardiac transplantation with no deaths.

Although the risk of a third myocardial revascularization is low, this is not a procedure that is recommended lightly. Patients should have myocardial ischemia with symptoms that are refractory to maximum medical therapy. The minimum acceptable degree of left ventricular function has not been clearly defined, but when there is clear evidence of profound left ventricular dysfunction cardiac transplantation should be considered as an alternative mode of treatment. Inadequate or incomplete revascularization will give rise to suboptimal results, so the patient should have distal vessels that are of reasonable quality and size to allow grafting and significant improvement in myocardial perfusion.

The timing of operation requires considerable judgment. There are no hard data available for critical analysis, but it seems advantageous to operate, whenever possible, only after a maximal effort to stabilize the patient's myocardial ischemia. This may require several days of intensive management with intravenous heparin and nitroglycerin plus aspirin.

As mentioned previously, the femoral vessels are not routinely exposed before the sternotomy incision. An oscillating saw is used in all patients. Minimal dissection is undertaken to expose the ascending aorta and right atrium. Single aortic and atrial cannulation is preferred, but if there is inadequate room on the aorta for arterial cannulation the retrograde femoral approach is em-

ployed. Early heparinization and cannulation are preferred, with most of the dissection of the heart performed once cardiopulmonary bypass has been established. Existing vein grafts are left alone as much as possible. They are neither ligated nor excised.

Internal mammary artery grafts are used whenever feasible, sometimes as free grafts if the anastomotic site on the coronary artery is quite distal. Greater saphenous vein is used as an alternative, as is lesser saphenous vein if there is inadequate length of greater saphenous vein available.

Crystalloid cardioplegia administered antegrade in the aortic root has been employed in the routine fashion. Recently retrograde cardioplegia delivery through the coronary sinus has been used in patients in whom there are obvious or suspected problems with cardioplegia delivery. If there is a patent IMA bypass graft it is carefully protected, and it is clamped with a small soft metal vascular clamp once cardioplegia delivery has been initiated. The aortic cross-clamp usually remains in place until all distal and proximal anastomoses have been performed.

All 12 of the hospital survivors had complete relief of their chest pain early postoperatively and were rendered asymptomatic. The average pain-free interval after their third coronary artery bypass operation was 31 months in the 8 patients in whom recurrent symptoms have developed. Long-term follow-up has demonstrated overall good results with no late deaths. However, one third of the long-term survivors have experienced a late postoperative myocardial infarction.

This series demonstrates that third-time coronary revascularization can be performed with low morbidity and mortality. This group has experienced satisfactory relief of symptoms and no late mortality. Patients who experience symptoms of myocardial ischemia that are refractory to maximal medical management and who have distal vessels amenable to revascularization and reasonably well preserved left ventricular function should be given careful consideration for third-time coronary artery revascularization.

DISCUSSION

DR HUGH VAN GELDER (St. Petersburg, FL): We recently had a patient in whom we did a third-time redo operation and at the site of the IMA takedown the left ventricle was plastered to the chest wall. Do you do anything to make it easier to come back, either using a membrane or trying to close pericardium to make the operation easier the next time?

DR KEVIN D. ACCOLA (Memphis, TN): I enjoyed your report. I just wanted to make a couple of comments as well as ask you a technical question. We recently reported our reoperative coronary experience from Emory, which was published in *The Annals* in October 1991. In our group we had 53 patients who had either a third or fourth reoperative procedure. Our mortality was the same as yours, 7.5%. Of interest, we also noticed that there was a very short interval between the reoperations in this particular patient population. Between the first and second bypass procedures was 5.26 years, between the second and third was 8.88 years, and between the third and fourth was 4.65 years. Possibly you could expand on these findings as to your thoughts on the cause of the short reoperative period. Do these patients have a more aggressive coronary artery disease process? They did not appear in our review to have any higher incidence of risk factors than usual.

From a technical standpoint, we typically on the second reoperative procedure expose the femoral artery, and on the third and fourth procedure we will usually cannulate the femoral artery and sometimes the vein. How do you decide in which patients you are going to proceed with femoral artery cannulation; is it when you get into a problem during sternotomy or electively?

My final question is in regard to existing vein grafts. We typically at 5 to 7 years will replace a vein graft depending on its clinical appearance either from the preoperative angiogram or at the time of reoperation. What are your criteria for replacement of existing veins and how do you evaluate them, or do you empirically replace these grafts at a predetermined time?

DR LENOX D. BAKER, JR (Norfolk, VA): I was impressed that 85% of your patients were still smoking, and this may answer the question Dr Accola just asked about why the interval is so short. Do you think the situation is similar to that of drug addicts who are still active drug users and come in infected, in whom we do not do second valve replacements? I wonder, considering these results, which are really basically poor long-term results, whether we should consider not doing a third operation until the patient has made some commitment to get off cigarettes and proven it, which is what we also do with our heart transplant recipients. We do not perform transplantation in people who are still smoking. Perhaps we should not do a third coronary artery bypass in a patient who continues to smoke.

DR GEORGE R. DAICOFF (St. Petersburg, FL): I have been listening to these last two reports and I am a little bit confused because we thought that an IMA offered an additional degree of protection and subsequently thought we should do as many arterial grafts as possible. Then we learned that there was a higher incidence of infection when using bilateral IMAs. So then we reverted to uniformly using one IMA and some veins. I am currently experiencing 20% or more redo operations in my

practice; do you now believe we should save the second IMA for the redo? Is there really evidence that two IMAs offer more long-term protection than one IMA and a vein at the initial operation? What are your thoughts about that?

DR MERRILL: I thank all of you for your comments. I will try to answer your questions in order. Certainly adhesions are a major problem in these multiple reoperative procedures. We have not used any of the artificial pericardium or biological forms of pericardium and have for the most part found that it does not seem to make a large difference whether the pericardium is closed or left open. I think the only thing that is really important is to make sure at the time of operation that the bleeding is well controlled and the mediastinum is well drained, and we do make a point of washing the talc off our gloves before every operation in the hope that the absence of talc will lead to less adhesion formation.

Doctor Accola, I am very familiar with your excellent article that was published recently regarding the results at Emory. Clearly, I think these patients do have an aggressive form of coronary artery disease as manifested by their early age at first operation and their fairly rapid requirement for subsequent operations. I really do not have an explanation as to what the factors might be that cause this problem, although clearly the persistence of smoking is a major issue and a major concern. As I mentioned, we do not routinely expose the femoral artery or vein but go ahead and perform the sternotomy and just make a decision at the time of operation as to whether or not there is in fact room on the ascending aorta for arterial cannulation. Also, one has to contemplate the grafts that are already present plus the new proximal anastomoses that will have to be performed. But we will perform femoral cannulation only when there does not seem to be sufficient room on the ascending aorta.

With regard to replacing patent but older vein grafts on the heart, I think that is a matter of considerable judgment. As a general rule, I think the older grafts should be replaced if possible, even if they are patent. We all know that they commonly contain considerably more atherosclerotic disease than is apparent on the arteriogram. The key factor to consider is what you are going to replace the conduit with. Does the patient have sufficient remaining good-quality artery or vein that will be better conduit than what is already present? Again, I think that calls for considerable individualized judgment.

With regard to Dr Baker's comment, I really do not know how tough we should be on these people who are persistent smokers. Certainly that is one of the risk factors that could be modified, but a fair number of them are overweight, they do not really follow regular exercise regimens, and they do not follow proper low-cholesterol, low-fat diets. So there are many aspects to their illness that need to be addressed, and we will all need to be thinking about these factors in the future.

With regard to the last point, I must admit I am really not sure exactly what the proper philosophy of IMA use should be. We are learning more and more that multiple IMA bypass grafts and extended IMA bypass grafts may in fact be good, they may prolong survival, and perhaps we should be using the IMAs more extensively in the hope of preventing reoperation, but I think it will be a long time before we have the definitive answer.

Penetrating Injuries of the Aortic Arch and Its Branches

James W. Pate, MD, F. Hammond Cole, Jr, MD, William A. Walker, MD, and Timothy C. Fabian, MD

Section of Cardiothoracic Surgery, University of Tennessee, and Elvis Presley Trauma Center, Memphis, Tennessee

Acute cardiac failure, pulmonary edema, and ischemia of the brain, cord, and other structures pose special problems with trauma to the aortic arch and its branches. Data on 93 such cases are reported. Diagnosis was made by clinical examination in hemodynamically unstable patients and led to immediate operation in 61.3%. Patients in stable condition had angiography, which localized the injury and allowed planning of incision and bypass shunts. In left subclavian artery injuries, anterior thoracotomy was best for proximal control regardless of wound entry sites; midline sternotomy with sternocleidomastoid extension was usually adequate for other

vessels. Flow was reestablished in all carotid injuries; there were no neurological complications. Temporary or permanent bypass shunts during periods of proximal aortic occlusion were valuable in decreasing cardiac afterload, maintaining circulation to the brain, and allowing an unhurried methodical approach to the hematoma. Occlusion of one or more venae cavae alleviated acute cardiac dilatation during brief periods of ascending aortic clamping. Associated trauma contributed to the high mortality.

(Ann Thorac Surg 1993;55:586-92)

Pulmonary edema, acute heart failure, and irreversible ischemia of the brain, spinal cord, kidneys, and viscera are special problems associated with control of exsanguinating hemorrhage from penetrating trauma to the aortic arch and its branches. Many injuries localized to the anterior surface of the arch or its branches (more than a centimeter distal to their origin) can be easily repaired by simple digital pressure or partial occlusion and suture, whereas more complex injuries involving the posterior surface of the arch or the origin of innominate or carotid arteries may require bypass techniques to avoid these potentially fatal complications. Surgical approaches should be directed at decreasing cardiac afterload and maintaining oxygenated blood flow to the brain and distal body.

For these purposes, Symbas and Sehdeva [1], in 1970, reported the use of a temporary shunt from the ascending aorta to the innominate artery for repair of a stab wound of the arch. This concept was extended in 1973 by DeMeester and associates [2], who used a heparinized shunt from the ascending aorta to the femoral artery to maintain distal circulation and decompress the heart during repair of an arch injury. Rather than temporary shunts, the Houston group [3], in 1982, introduced the use of a permanent prosthetic bypass graft from the ascending aorta to the distal carotid or innominate artery before repair of the arch and innominate artery. In 1984, we adopted the routine use of both temporary and permanent bypass shunts for managing these injuries and expanded the use

to Y grafts to both carotid arteries before disturbing the hematoma or attempting repair.

These injuries are uncommon [4, 5]; Rich and associates' report [6] of 1,000 arterial injuries from the Vietnam war includes only three innominate and eight subclavian artery injuries. The development of well-organized trauma systems is leading to increasing numbers of such victims of urban warfare reaching the treatment facility alive.

To summarize our experience and arrive at reasonable recommendations, we are reporting our more recent experience of penetrating injuries to the aortic arch (from superior pericardial reflection to the aortic isthmus) and its branches—innominate, common carotid, and subclavian arteries—that we treated at their initial trauma episode during the 8 years ending September 1, 1992. Only carotid artery injuries that resulted from thoracic wounds or wounds of the base of the neck or supraclavicular spaces that passed into the thorax are included.

Material and Methods

We reviewed the medical records of 93 consecutive patients who sustained penetrating injury (63.5% of which were gunshot wounds) of the aortic arch and its branches and were admitted to the Elvis Presley Trauma Center, Memphis (Table 1). Most patients (79.7%) were male; they had a median age of 26 years. Among the factors studied were age, mechanism of injury, hemodynamics, preoperative and postoperative neurological findings, associated trauma, diagnostic methods, anatomy of vascular injury, surgical exposure, use of shunts, and mortality. When there was evidence of massive or pulsatile bleeding or persistent hemodynamic instability, the patient was im-

Table 1. Clinical Outcomes of Entire Series

Site	Number	Not Resuscitated	Operated Patients		Total Survivors
			Lived	Died	
Aorta	27	9 (33.3%)	11 (61.1%)	7 (38.9%)	11* (40.7%)
Innominate	6	...	5 (83.3%)	1 (16.7%)	5 (83.3%)
Carotid	31	3 (9.7%)	25 (89.3%)	3 (10.7%)	25 (80.6%)
Subclavian	29	...	25 (86.2%)	4 (13.8%)	25 (86.2%)
Total	93 (100.0%)	12 (12.9%)	66 (81.5%)	15 (18.5%)	66 (71.0%)

* Four deaths resulted from other injuries. Excluding these, survival related to the aortic arch injury alone for operated patients would have been 83.3%.

mediately operated on without further study. All patients in stable condition demonstrating pulse deficit, major hematoma, widened mediastinum, or missile tracts thought to be near major arteries had aortograms for precise anatomical diagnosis and to plan surgical exposure and the possible use of shunts ("selective" operation). Operating rooms and an arteriographic suite are integral to the Trauma Center, thus avoiding unnecessary and dangerous transportation of these patients in critical condition.

Operative Technique

The two basic incisions usually used were (1) midline sternotomy, with cervical extensions over one or both carotids when needed, and (2) an anterior left thoracotomy through the fourth intercostal space (with dislocation of cartilage) for exposure of the left subclavian artery. The latter incision was extended by partial median sternotomy, neck incision, and excision of half the clavicle, as required. Entrance wounds in the left supraclavicular fossa and associated with a left pneumothorax or hemothorax were assumed to be subclavian artery injuries for purposes of selecting the incision. When an arteriogram was available, the plan of the operation was based on the site of vascular injury. In the group having immediate operation, the operative approach was chosen based on suspected injury and the exact technique was modified as necessary after the chest was open.

Injuries on the anterior surface of the arch or branches further than 1 cm away from the aorta were usually managed by digital pressure or tangential partial occlusion clamps and suture. Intermittent aortic occlusion, either partial or complete, and caval occlusion were useful adjuncts both for exposure and for decreasing blood pressure while suturing. For larger wounds and gunshot injuries, large felt pledgets or patches of prosthetic material were used. With involvement of the superior surface of the arch and origins of the innominate or carotid arteries, more complex procedures were usually considered necessary.

When exposure of the concavity and posterior surface of the aorta was necessary, the pulmonary artery and aorta were separated by sharp incision, followed by division of the pericardial and fascial tissue from *within* the pericardium (Fig 1). Dissection of the concave and posterior surfaces of the arch from *outside* the pericardium is hazardous, as the fibrous layer of the pericardium

blends into and forms the aortic adventitia. Dissection from without leads to an apparent cleavage plane, which may actually be within the aortic wall [7].

Principles aimed at avoiding irreversible ischemic damage to vital organs or distension of the left ventricle were followed (Table 2). When practical, blood flow to the distal arterial bed was always reestablished. When a *midline* incision was used, the pericardium was immediately opened vertically, before the hematoma was entered. This allowed tapes to be easily placed around the cava(e) for cardiac inflow occlusion and around the ascending aorta for temporary partial occlusion while the repair was effected. While bleeding was controlled by the hematoma or by digital pressure, distal control of the carotid artery (or arteries) was obtained. When compromise of carotid flow was anticipated, shunts were established *before* disturbing the hematoma or bleeding site (Fig 2). This allowed both decompression of the aorta and left heart and flow to the brain during vascular repair. The proximal end of a graft or shunt was placed into the intrapericardial aorta and the other end was placed in the carotid artery distally, before the hematoma was entered. When grafts were used, they were left in situ as bypass grafts; temporary shunts were removed when the repair

Fig 1. Exposure of the concavity and posterior surface of the aortic arch begins with dissection from within the pericardium (see text).

was completed. Although available in the Trauma Center, cardiopulmonary bypass was used in only 1 patient (patient 3).

When the injury involved the origin of the innominate or carotid artery, the bypass prosthetic graft was left in place permanently and the end of the carotid was oversewn. When the injury did not involve the origin of the branch vessel or continued hemorrhage was a problem, a temporary shunt (see Fig 2) with primary repair or interpositional prosthesis became the preferred technique; this was faster and led to use of less prosthetic material in the narrow confines of the thoracic inlet. The intrathoracic carotid was never ligated without bypass grafting. Primary repair was done when feasible [8].

Illustrative Cases

Both the applications of these principles and some difficulties in their use are illustrated by the following three case reports.

PATIENT 1. A man sustained a stab wound in the right supraclavicular space. Initial pulsatile bleeding was controlled by pressure. Aortogram revealed injury to the aortic arch at the base of the innominate and left carotid arteries. There was associated filling of the left innominate vein and superior vena cava. Repair involved bypass Y shunts to both common carotid arteries followed by brief, intermittent periods of aortic cross-clamping and partial caval occlusion, while the aorta was repaired with pledgeted sutures (see Fig 2). The innominate veins were repaired by simple suture. There were no major complications.

PATIENT 2. This man had a gunshot wound to the left chest. Emergency anterolateral thoracotomy for massive bleeding revealed through-and-through wounds of the aortic arch. The anterior aortic wound and lung were repaired, while the posterior aortic wound was tampon-

Fig 2. (Patient 1.) Bypass shunt from ascending aorta to carotid arteries is established before attempting suture of the arch. An injury to the posterior surface of the junction of the brachiocephalic veins and the caval tapes are not shown.

aded. A midline incision was necessary for adequate exposure of the posterior aortic wound. The pericardium between the aorta and pulmonary arteries was divided, followed by division of the posterior fascial attachments of the aorta. Exposure and repair of the posterior defect was done in intermittent steps by temporary tape occlusions of aortic branches, intrapericardial control of the aorta, and periods of venous inflow occlusion (Fig 3). Although the patient later died of complications of prolonged shock, this case is useful in emphasizing the necessity for exposure of the posterior arch from the midline. Had the location of the posterior wound been known before the necessary emergency thoracotomy, use of partial cardiopulmonary bypass may have been of benefit.

PATIENT 3. This man sustained a stab wound in the right supraclavicular space with a hunting knife; an aortogram demonstrated a large aorto-left innominate vein fistula. The groin vessels were exposed as a midline thoracotomy was begun. Massive bleeding was encountered upon opening the supramanubrial fascial space; cannulation was performed and partial cardiopulmonary bypass was begun before the sternum was divided. Pressure controlled the hemorrhage while the pericardium was opened and the incision extended along the left carotid sheath. Ascending aorta, superior vena cava, and neck vessels were controlled with tapes. The left innominate vein was almost severed; it was divided, allowing visualization of the anterior and superior surfaces of an extensive aortic laceration (Fig 4). Full cardiopulmonary bypass through the right atrium was instituted with systemic

Table 2. Surgical Principles Used In Repair of Aortic Arch Injuries

Principle	Application
Local control	Pressure only
Proximal control	Intrapericardial
Distal control	Tapes: aorta, carotid(s), & innominate
Maintain flow ^a	Bypass shunts:
From ventricle (1 min)	ascending aorta to
To brain (5 min)	carotid(s)
To cord, viscera (30 min)	
Prevent hypertension of left ventricle, pulmonary veins, central veins, cerebrospinal fluid	Arterial shunts and caval occlusion
Exposure of injury site	After proximal and distal control
Reestablish distal circulation	Repair or graft

^a Time of occlusion of arterial flow was kept below indicated times whenever feasible. Hypothermia allows some safe prolongation.

hypothermia and with cold cardioplegia. The ascending and descending aorta were cross-clamped (at 25°C), and the aorta was dissected and repaired with pledgeted sutures. Aortic cross-clamp time was 19 minutes, followed by 15 minutes of unclamping and then another 22 minutes of reclamping. The patient made an uneventful recovery.

Although this patient could have been handled as patient 2, cardiopulmonary bypass allowed a more controlled situation. Both patients could have benefited from

Fig 4. (Patient 3.) Large laceration of left innominate vein and aorta, with functioning arteriovenous fistula. Repaired with hypothermic cardiopulmonary bypass.

temporary bypass shunts from the ascending aorta to the distal carotid arteries, but shunts were not used in either because of the inability to control hemorrhage without occlusion of the ascending aorta after the chest was opened.

Repair of all major vein injuries has been our policy since 1964; however, this has not always been feasible without an intervening graft, which we did not use in the acute trauma setting. No caval ligation was done, although several cavae and innominate veins were sutured without problems.

Results

Associated injury was present in most patients (Table 3) and accounted for several of the deaths.

Fifty-seven patients (61.3%) were hemodynamically unstable; 12 of them (12.9%) died during attempted resuscitation before definitive operation (see Table 1). All had

Table 3. Associated Injuries to Other Structures

Injury to	Number	Percent
Major vein	21	22.6
Trachea	8	8.6
Esophagus	7	7.5
Lung	7	7.5
Spinal cord	6	6.5
Bracheal plexus	5	5.4
Heart	4	4.3
Abdomen	4	4.3
Total (includes other injuries)	77	82.8

injury of the aortic arch, proximal carotid artery, or both. The other 45 unstable patients were immediately operated on without angiograms.

In the 36 patients in stable condition operation was delayed until angiography was performed. Arteriovenous fistulas were demonstrated in 4 of these. In 4 patients not having angiograms, the incision was suboptimal and sternotomy became necessary. Three of these had emergency anterolateral thoracotomies for relief of cardiac tamponade. Another patient with massive left hemothorax was explored through a left posterolateral thoracotomy, but exposure of the posterior arch was not possible and a midline thoracotomy became necessary (patient 2).

All *aortic* injuries were repaired, usually with direct suture over felt pledgets, but on several occasions with prosthetic patches to avoid undue tension on the sutures. Digital pressure or partial occlusion clamps were usually adequate for control during repair. Of 18 patients who underwent operation, cardiopulmonary bypass was used in 1, aorto-carotid shunts in 3, and aorto-innominate shunts in 3. No such adjuncts were used in the other 11 patients, whose injuries were repaired without significant periods of carotid occlusion. Of the 18 patients who reached the operating room alive, 11 survived. Four patients died of other trauma: 1, of an extensive gunshot wound to the heart; 2, of abdominal injuries; and 1, of tracheal injury and asphyxia (see Table 1). Considering only the aortic injury (ie, hemorrhage, operating room deaths, cardiac malfunction, and neurologic complications), the injury-specific survival rate after surgical repair of aortic arch injuries themselves was 83.3%.

All *innominate artery* injuries were repaired or bypassed; only 1 patient died, unrelated to hemorrhage or complications of the innominate artery injury. None had neurologic defects. Bypass shunts were used in 4 patients who had shunts from the ascending aorta, and 1 had a bypass shunt from carotid artery to carotid artery before the chest was entered.

Three of the 31 patients with *common carotid artery* injury were agonal on arrival and definitive therapy was not possible before death. Two of the 28 patients operated on had obvious hemiplegia on admission; there was no improvement after operation. Twenty-six of the 28 patients survived to have carotid artery repairs. Bypass shunts, four permanent and one temporary, were used in these patients. No new or worsening neurologic symptoms developed in any patient after repair or grafting of the carotid artery. Two patients, both in profound shock, died on the operating table of associated injuries and could not be neurologically evaluated.

Of patients with *subclavian artery* injuries, half had primary repair; in 1 the subclavian artery was ligated and in the others it was repaired using grafts. Distal arterial flow was good in all patients. Two patients who had major venous trauma had residual edema of the arm after ligation of subclavian veins; this slowly improved over many months. Concomitant brachial plexus injuries were crippling in 3. The only amputation was of a single finger.

Comment

This retrospective, uncontrolled analysis of a group of patients with a broad spectrum of major injuries and of varying clinical status precludes meaningful statistical analysis. Although the general policies of Table 2 were in use during this series, they could not always be followed. Even with 27 years' experience with similar injuries [9] before this series, details of surgical management still changed during this period. Simplification of incisions and more use of bypass shunts were the major evolutionary changes during these 8 years.

Pulse deficits were of little diagnostic help in these patients; they were noted in only a few patients with firearm injuries of the subclavian artery. Hematomas of the base of the neck or gross arterial bleeding were of no aid in identifying the site of vascular injury. Unilateral hemothorax was usually of help in delineating the injury. The major indication for aortogram was known or suspected wound entry into the mediastinum or base of the neck. When the patient was in stable condition, aortograms were of great help, not only in diagnosis, but especially in planning the operation. In the selective group, we routinely did esophagograms only in those whose entry wound was in the base of the neck. Most of these patients were too uncooperative, either from trauma, drugs, or alcohol, to safely have an esophagogram. Of the seven esophageal injuries, six were repaired at initial operation and one was not diagnosed until serious postoperative infection occurred.

About a fourth of all patients had simultaneous major venous injuries, and an arteriovenous fistula was demonstrated in 4 of the 36 patients (11.1%) who had arteriograms. If the same incidence were true in those patients who did not have an arteriogram, one could expect as many as nine or ten fistulas. A significant correlation of arch injuries and arteriovenous fistulas has also been noted by others [7].

Large vein-ways in the legs, an arterial catheter in the right radial artery, and the use of autotransfusion devices are important basics in the management of these patients.

In previous years we frequently used a Sauerbruch incision for exposure of the innominate and subclavian arteries; its use has steadily diminished. A midline sternotomy with sternocleidomastoid extensions was usually adequate for the innominate artery; a posterolateral thoracotomy served for most of the left subclavian artery injuries resulting from thoracic wounds. However, wounds of the base of the neck involving the left subclavian arteries and extending into the thorax are usually best managed by anterior thoracotomy for proximal control of the artery, a supraclavicular incision with division of the sternocleidomastoid muscle, and clavicular resection as needed for distal control and repair. A full Sauerbruch incision may be necessary if still further exposure is needed.

The issue of ligation versus reconstruction of the carotid artery has received much attention in the literature. In 1974, it was demonstrated [10] that repair of the intrathoracic carotid artery could be associated with massive

cerebral infarction. By 1991, it had become obvious that about half of the deaths after innominate and carotid injuries were due to cerebral infarction caused by *ischemic*, not reperfusion, infarction [11]. Our experience leads us to recommend bypass shunts from the intrapericardial aorta to one or both carotid arteries before exposing the bleeding site when injury to innominate or intrathoracic carotid artery is known or strongly suspected. Only about 20% of patients have a "normal" circle of Willis; preoperative and intraoperative shock and hypoxia contribute to cerebral ischemia, and there is high probability of prolonged occlusion of the carotid artery during dissection and vascular repair. Fabian and associates' [8] recent extensive review of the literature and their experience with a large series of carotid injuries led to conclusions that (1) there is no valid reason to avoid carotid artery reconstruction, (2) there are some patients in whom other impairments (eg, alcohol, drugs, shock) prevent proper preoperative neurological evaluation, (3) there are some patients with neurologic defects whose condition may actually improve after revascularization, and (4) patients with preoperative neurologic defects are seldom, if ever, harmed by reconstruction. None of the patients in this series had worsening neurologic status after flow was reestablished. The fear of "hemorrhagic infarct" of the brain after reestablishing carotid artery flow seems misfounded.

A careful study of the use of shunts has not been possible because of the rarity of these injuries. A recent report [12] of 30 years' experience with the use of shunts in 31 patients with penetrating (24) and blunt (7) injuries of the innominate artery, however, leaves little doubt that this should now be the accepted method of management.

There is a widespread aversion to the use of systemic heparinization in the severely injured patient. In this series of penetrating trauma, we used systemic heparin in doses of about 100 to 150 U/kg, while temporary shunts were in use or when a patient's carotid artery was occluded. We have used full systemic heparinization (300 U/kg initial dose) in more than 100 cases of blunt injury of the thoracic aorta or carotid artery. Most of these patients had concomitant injuries, including head, liver, or spleen disruptions. We have been unable, in spite of prospective critical observation, to demonstrate clear deleterious effects of short-term heparinization, except in patients with severe pulmonary contusions. Others have reported similar experiences [13].

During brief periods of aortic occlusion, the left ventricular afterload abruptly rises. Ventricular dilatation and resultant damage to the myocardium is a real threat. Continuous observation of the electrocardiogram and heart is necessary during these periods. Bradycardia usually occurs as the heart dilates. When a heartbeat drops to 50/min or electrocardiographic signs of ischemia evolve, the occlusion should be released as quickly as possible. In our clinical experience, and in the literature, the deleterious effects on the heart seem to be ameliorated by simultaneous caval occlusion. We have confirmed this in the animal laboratory (Van Voorst and Pate; unpublished results). Theoretically, the beneficial effects of caval occlu-

sion should extend to the lungs and cerebrospinal fluid pressure. Hypovolemia, as suggested by the work of Martin and associates [14], is probably beneficial until repair is complete.

Elevated central venous pressure results in elevated cerebrospinal fluid pressure with consequent decrease in blood flow to the central nervous system. With aortic occlusion resulting in such an increase in cerebrospinal fluid pressure, superimposed on decreased carotid blood flow during clamping, cerebral ischemia is increased on the clamped side and unilateral cerebral edema on the unclamped side might be expected. Hypovolemia, again, might help prevent this effect.

Essentially all of these patients remained on mechanical ventilation for more than 24 hours and most showed varying evidence of pulmonary dysfunction. Shock and massive intravenous fluids are major factors in the disturbed physiology, but the rise in pulmonary venous pressure with partial aortic occlusion certainly might contribute. Again, brief periods of caval occlusion or hypovolemia should be of value in alleviating pulmonary damage. Robicsek and Matos-Cruz [15] recently used electrically induced ventricular fibrillation for these purposes.

Postoperative paraplegia, which occurs in up to 35% of cases of occlusion at the distal arch required for repair of traumatic rupture of the aorta, was not recognized in these patients with penetrating wounds. This is probably due to the fact that periods of proximal aortic occlusion long enough to produce cord damage resulted in fatal cardiac dilatation or cerebral ischemia.

Although patient 3 had a favorable outcome after the use of cardiopulmonary bypass, we believe that most patients (91/93) were more expeditiously managed by the use of arterial bypass shunts and brief caval and aortic occlusion. Retrospectively, in only 2 patients, both with large through-and-through gunshot wounds of the arch, do we believe that cardiopulmonary bypass would have been of value. In both patients necessity for prompt control of the hemorrhage precluded use of cardiopulmonary bypass, even though only 30 to 45 minutes are needed for its set-up.

We thank Jean Distretti, RN, Service Manager, and her staff in the Data Processing Unit of the Elvis Presley Trauma Center for their valuable contribution in data collecting and tabulation.

DISCUSSION

DR HOOSHANG BOLOOKI (Miami, FL): I enjoyed this presentation very much and had the privilege of reading the manuscript earlier. I would like to congratulate Dr Pate and associates for doing admirable work on these very ill patients. This series of 93 patients actually is one of the largest reported series in the world literature. We have had an experience similar to this but not in as many patients. We have our experience summarized in a chapter in a book titled *Trauma Management* edited by the late Dr Kreis [1]. We entirely agree with your recommendations in managing this injury.

The points that you bring up, and I think they should be reemphasized, are mainly three. First, control the bleeding as fast as you can; second, establish blood flow distally if at all possible and do not just tie off the artery; third, during hypotension periods either incidentally (or because of clamping the vena cava, as you have suggested, and it is a very good idea) continue to work aiming at control of bleeding specifically around the aorta itself and the aortic arch. In other words, use the hypotensive periods to the patient's advantage by controlling the major branches of the arch.

I think it is important to note, as you are indicating, that the farther away the injury is from the arch the greater is the need for a shunt or some kind of bypass. Conversely, for injuries on the aortic arch, especially around the arch or behind the arch, heart-lung bypass is needed. There is no doubt that a heart-lung machine is used in a small number of these patients. It is used more often when angiography delineates the lesion and the operation is planned. In fact, we have lost some patients due to central or arch injuries because we did not have an angiogram. Such a study cannot be done in a patient who is bleeding out, as you indicated already, and as a result one does not know the extent or location of the injury. I think it is important to do a very good physical examination, especially if the injury is a day or two old. A systolic murmur is an important finding because that would allow for better patient management and work-up. The murmur may point to the presence of an arteriovenous fistula. An angiogram, whenever possible, is an invaluable guide to location of injury and hence the method of management.

I have three questions. First, what would you do with an enlarging mediastinal hematoma if the patient is in stable condition and the aorta is intact? Would you explore it or leave it alone and treat the patient conservatively? Second, if there is an acute brain injury (or mild stroke) due to a carotid lesion (cut-off by a flap or by external pressure but without acute carotid bleeding)

would you reestablish the blood flow to the distal carotid artery, or if the neurologic dysfunction is not serious would you wait and intervene at a later time, say a few weeks? Third, around the aortic arch there are many nerves, especially the phrenic, vagus, and recurrent laryngeal. I have had at times problems with these patients after I have done a successful operation on the arch in that they have been respirator dependent. Have you had any problems with that, and what special maneuvers do you use to identify these nerves in the bulk of the hematoma? I thank you again for a fine presentation and congratulate you for good work.

DR PATE: I appreciate your comments, Dr Bolooki. First, a mediastinal hematoma in a patient in stable condition is a definite indication for aortography; most of the time, a major vascular injury will be seen. When an aortogram cannot be obtained, consideration must be given to surgical exposure.

In relation to aortic injuries, we cannot answer the question about completed strokes because, even though this is a very large series, we had too few strokes. There is a lot of information in the literature in relation to neck injuries. As far back as 1974, it was known that revascularization of the carotid artery could result in hemorrhagic infarction. By 1991, it was obvious that about half of the deaths after carotid trauma were due to cerebral infarction, usually *ischemic*. The fear of reperfusion infarction after carotid injury repair is probably based on a myth. An occasional patient will show some improvement after reconstruction. Confusing the issue is the fact that many of these patients are in shock or under the influence of alcohol or drugs and cannot be evaluated preoperatively. Yes, circulation should always be reestablished regardless of neurological findings.

Most of the time, the phrenic nerve can be identified by feel as the hematoma displaces it medially and anteriorly. The reasons for the difficulty in getting a patient off the ventilator place us in the area of opinion rather than facts—I could preach a sermon. Most of these patients are “drowned” during the resuscitation process with 18 to 20 L of crystalloid. They have many reasons for difficulty in weaning. I do not believe this is unique to phrenic or recurrent nerve injury.

DNA Ploidy Pattern of Each Carcinomatous Component in Adenosquamous Lung Carcinoma

Yukito Ichinose, MD, Nobuyuki Hara, MD, Shinzo Takamori, MD,
Kazunobu Maeda, MD, Tokujiro Yano, MD, and Mitsuo Ohta, MD

Department of Chest Surgery, National Kyushu Cancer Center, Fukuoka, Japan

The relationship between adenocarcinomatous and squamous carcinomatous components in 12 surgically resected adenosquamous lung carcinomas was analyzed using DNA flow cytometry. Well-preserved parts of the tumor showing either adenocarcinoma or squamous cell carcinoma were identified on paraffin blocks. The cells obtained from each component were stained with propidium iodide for DNA flow cytometry. In the analysis of DNA flow cytometry, both components in the same tumor were defined as being related to each other when

they showed diploidy or when at least one DNA index of abnormal clones between two aneuploid components was identical. According to these criteria, 8 (67%) of the 12 tumors showed a relationship between adenocarcinomatous and squamous carcinomatous components. This suggests that, despite the different phenotypes, both components of some adenosquamous lung carcinomas may share similar biological characteristics.

(*Ann Thorac Surg* 1993;55:593-6)

Adenosquamous lung carcinoma is rarely seen compared with other histologies such as squamous cell carcinoma, small cell carcinoma, large cell carcinoma, and adenocarcinoma of the lung. The incidence reported in surgical resection series [1, 2] is only approximately 2%. Thus, the biological behavior and clinical characteristics of adenosquamous lung carcinomas have not been well described.

Recent studies indicate that all lung cancers, including mixed cell types, arise from a common stem cell [1]. Therefore, one of the most interesting questions about the biological behavior of adenosquamous lung carcinoma is whether the adenocarcinomatous and squamous carcinomatous components in the same tumor share some similar biological characteristics. In the present study, we used DNA flow cytometry to examine this issue.

For editorial comment, see page 576.

Material and Methods

The lung tumors of 19 patients who underwent pulmonary resection at National Kyushu Cancer Center from June 1979 to May 1990 were diagnosed as adenosquamous lung carcinoma. According to the pathological criteria of the Japan Lung Cancer Society [3], tumors identified as adenosquamous carcinoma of the lung should show well-defined squamous components (ie, intracellular keratin or intercellular bridges) and adeno components (ie, glandular, tubular, or papillary structure) on routine microscopic

examination using hematoxylin and eosin staining. In addition, each component should occupy at least 20% of the tumor area obtained by cutting the tumor so as to expose the largest tumor surface. Although the 19 resected tumors fulfilled these criteria, 6 tumors were excluded before DNA flow cytometric analysis because of a lack of suitable specimens. Pathological staging was done according to the new international staging system [4]. Survival after operation was recorded as of September 1991.

Flow cytometric analysis of cellular DNA content was performed using paraffin-embedded blocks of 13 surgically resected tumors. Well-preserved areas of the tumor showing either adenocarcinoma or squamous cell carcinoma were chosen on slides, and the corresponding areas on the paraffin blocks were identified. A single cell suspension was made, and the cells were stained with propidium iodide according to the method described by Tosi [5], Vindeløv [6], and their associates. The stained cells were analyzed on a fluorescence-activated cell sorter-CAN analyzer (Becton Dickinson, Mountain View, CA). At least 20,000 cells from each specimen were examined, and the DNA content per cell, measured by fluorescence intensity, was recorded and displayed in a histogram. The resulting DNA histograms were interpreted without knowledge of patient data.

The DNA index was calculated as the ratio of the aneuploid G_0G_1 peak to the diploid G_0G_1 peak. When only one G_0G_1 peak (DNA index = 1) was observed, the tumor was considered to be diploid. Tumors that had evidence of at least one distant G_0G_1 population (DNA index > 1.0) in addition to a diploid stemline were classified as aneuploid. The lowest peak was assumed to represent the diploid G_0G_1 peak (DNA index = 1). Samples in which the coefficient of variation of the diploid

Table 1. Summary of Data on Tumors With Similar DNA Ploidy Pattern

Patient No.	Pathological TNM Stage	Diploid Component or DNA Index in Aneuploid Component		Survival After Operation (mo)
		Adenocarcinoma	Squamous Cell Carcinoma	
1	T1 N0 M0	WD (20) ^a Diploid	MD (80) Diploid	Alive, 124
2	T1 N0 M0	MD (50) 1.767 ^b	MD (50) 1.733 ^b	Died without recurrence, 47
3	T2 N0 M0	MD (60) Diploid	MD (40) Diploid	Died, 26
4	T2 N0 M0	PD (60) 1.151, 1.566, 2.094 ^b	MD (40) 1.693, 2.080 ^b	Died, 10
5	T2 N2 M0	MD (20) Diploid	PD (80) Diploid	Alive with recurrence, 50
6	T2 N2 M0	MD (40) Diploid	MD (60) Diploid	Alive, 16
7	T2 N2 M0	MD (20) 1.983 ^b	MD (80) 1.862, 2.069 ^b	Alive with recurrence, 14
8	T2 N0 M1	WD (30) 1.949 ^b	MD (70) 1.950 ^b	Died, 3

^a Numbers in parentheses are percentages of largest cut surface area of tumor occupied by component.

^b There was an identical abnormal DNA index between two aneuploid components.

MD = moderately differentiated; PD = poorly differentiated; WD = well differentiated.

G₀G₁ peak exceeded 10% were not used to determine DNA ploidy of the tumor. Because of this, analysis of DNA ploidy of the adenocarcinomatous component of 1 tumor was not possible, and therefore, DNA ploidy patterns between adenocarcinomatous and squamous carcinomatous components in 12 tumors were compared. The coefficient of variation for the G₀G₁ peak of the diploid and aneuploid cells analyzed ranged from 3.2% to 9.8% (median value, 5.1%) and from 3.9% to 9.4% (median value, 4.7%), respectively. The size of the aneuploid population ranged from 6.3% to 34.1% (median size, 11.8%).

The adenocarcinomatous and squamous carcinomatous components in the same tumor were defined as being related to each other when they showed diploidy or when at least one DNA index of abnormal clones between two aneuploid components was the same or almost identical. The criterion that defined an identical abnormal clone between two aneuploid components was the following: mean DNA index of the subject clones $\times 0.975 < \text{DNA indices of each subject clone} < \text{mean DNA index of the subject clones} \times 1.025$.

Results

The adenocarcinomatous and squamous carcinomatous components in 8 (67%) of the 12 adenosquamous lung tumors were defined as being related to each other. Table 1 shows the DNA ploidy pattern and identical abnormal DNA indices of those components. Both components showed diploidy in 4 tumors. There was an identical abnormal clone between each of the two components in 4 tumors. Figure 1 shows two representative tumors' histologies and the corresponding DNA ploidy patterns.

The relationship between the adenocarcinomatous and squamous carcinomatous components in 4 tumors could not be found using the criteria of the DNA ploidy pattern. As shown in Table 2, the components of squamous cell carcinoma and adenocarcinoma in 3 tumors had DNA diploidy and aneuploidy, respectively. There was a dissimilar abnormal DNA index between two aneuploid components in 1 tumor.

Comment

The histogenesis of adenosquamous lung carcinoma remains unclear. There are many possibilities, including adenocarcinoma with squamous metaplasia, collision tumor, high-grade mucoepidermoid carcinoma, and bipotential undifferentiated cell origin [7, 8]. The study by Steele and Nettesheim [9] shed light on this issue. They examined two different mixed adenosquamous tumors derived from transformed F344 rat tracheal epithelium. The total of 20 clones that had been isolated from the two tumors were cultured and then inoculated into animals for the assessment of in vivo differentiation. Of the 20 single-cell clones, 15, 3, and 2 clones produced adenosquamous carcinomas, adenocarcinomas, and squamous cell carcinomas, respectively. These findings strongly suggest that a mixture of differentiated cell types in adenosquamous cell carcinoma does not result from a mixture of stem cells with one fixed phenotype in the tumor, but rather from instability of differentiation.

The criteria used here to determine the relationship between adenocarcinomatous and squamous carcinomatous components in the same tumor by DNA flow cytometry are based on the following two hypotheses: (1) In the case of both being diploid components, there are no

Fig 1. Histologic features and histograms of DNA flow cytometry of adenocarcinomatous and squamous carcinomatous components in surgically resected adenosquamous lung carcinoma. The abscissa and the ordinate in DNA histograms represent relative DNA fluorescence intensity and cell number, respectively. Histologically, patient 1 (see Table 1) had (A) well-differentiated adenocarcinoma and (B) moderately differentiated squamous cell carcinoma. Both components had DNA diploid patterns. Histologically, patient 8 (see Table 1) had (C) well-differentiated adenocarcinoma and (D) moderately differentiated squamous cell carcinoma. (All, hematoxylin and eosin; $\times 100$.) (* = identical abnormal DNA clone between two components.)

abnormal clones in terms of DNA ploidy, and thus their biological characteristics can be considered similar, and (2) when at least one DNA index of abnormal clones between two aneuploid components is the same or almost identical, both components can be thought to be related, in part, to each other. Our recent studies [10, 11] have shown that these criteria work for identifying the relationship between pulmonary metastases or recurrent tumors and primary tumors.

In the present study, we were able to demonstrate similar biological characteristics, in terms of DNA ploidy patterns, between the adenocarcinomatous and squamous carcinomatous components in 8 (67%) of the 12 adenosquamous lung carcinomas. The figure of 67% could be considered too high if adenosquamous carcinomas were composed of different stem cells. Therefore, this observation may lend support to the conclusion of Steele and Nettesheim [9].

The survival of patients who undergo surgical resection of adenosquamous lung cancer is variable [2, 12, 13]. In

Table 2. Summary of Data on Tumors With Dissimilar DNA Ploidy Pattern

Patient No.	Pathological TNM Stage	Diploid Component or DNA Index in Aneuploid Component		Survival After Operation (mo)
		Adenocarcinoma	Squamous Cell Carcinoma

2	T2 N2 M0	MD (20) 1.746	MD (80) 1.932	Died, 14
3	T2 N2 M0	MD (40) 1.534	MD (60) Diploid	Died, 26
4	T3 N1 M1	WD (50) 2.103, 2.466	PD (50) Diploid	Died, 17

^a Numbers in parentheses are percentages of largest cut surface area of tumor occupied by component.

MD = moderately differentiated; PD = poorly differentiated; WD = well differentiated.

our series, the 5-year survival rate is 20% for the 5 patients in pathological stage I, which is poor compared with that of patients with adenocarcinoma or squamous cell carcinoma. However, 3 of the 4 patients in whom both adenocarcinomatous and squamous carcinomatous components showed diploidy have survived 124 months (stage I), 50 months, and 16 months (both stage III) after operation. Whether analysis of DNA flow cytometry of the tumor is capable of identifying which patients with adenosquamous lung cancer have a good prognosis, as shown in adenocarcinoma or squamous cell carcinoma of the lung [14-16], should be investigated in the future.

This work was supported in part by a grant-in-aid for cancer research (62-S-1) from the Ministry of Health and Welfare, Japan.

We thank Ms Lesley Koustaff for critical review and Ms Yumiko Oshima and Ms Yuko Ishibashi for expert help in the preparation of the manuscript.

Recycling of the Internal Mammary Artery in Coronary Reoperation

Luc Noyez, MD, and Leon K. Lacquet, MD

Department of Thoracic and Cardiac Surgery, University Hospital Nijmegen St. Radboud, Nijmegen, the Netherlands

In 5 patients undergoing a coronary artery reoperation, the internal mammary artery graft was taken down and reused. No special problems were encountered perioperatively or postoperatively. Because the number of grafts and distal anastomoses performed in coronary reopera-

tions is increasing, lack of suitable graft conduits will be a problem in the future. Recycling an internal mammary artery graft may be an option to achieve good revascularization in some coronary reoperations.

(Ann Thorac Surg 1993;55:597-9)

Over the years, the number of grafts and distal anastomoses at reoperation has increased, whereas suitable graft material is limited [1]. The use of one internal mammary artery (IMA) or both IMAs in primary coronary operations leaves more saphenous vein available at reoperation. However, using IMAs in coronary reoperations provides more latitude in graft conduits [2]. With previous use of the IMAs as grafts, however, the specific problem of lack of bypass conduits can arise. Several alternatives to the great saphenous vein were tried, but the results were poor [3]. Recently, we have reused the left IMA (LIMA) in five coronary artery reoperations. Here we describe and discuss our experience with the "recycled" IMA in coronary artery reoperations.

Material and Methods

Patient Population

Between January 1987 and December 1991, 206 coronary reoperations were performed in our department. In 9 patients, the LIMA, the right IMA (RIMA), or both had already been used as grafts. In 5 patients (3 men, 2 women), we reused the LIMA at reoperation.

Preoperatively all 5 patients were in New York Heart Association functional class III. The mean age at reoperation was 63 ± 8 years (range, 58 to 70 years), and the mean interval between the first operation and reoperation was 51.6 ± 28.1 months. All patients had a family history of atherosclerotic heart disease, 4 had a history of smoking after the first operation, and 1 had insulin-dependent diabetes mellitus.

In 4 patients, the angiographic indication for reoperation was progression of atherosclerosis in the native coronary vessels and the venous grafts. One patient had an isolated graft failure, namely, a stenotic IMA graft to the left anterior descending coronary artery (LAD). This patient underwent reoperation 10 months after the first operation. The indication for takedown and reuse of the

LIMA graft to the LAD was a stenotic LAD anastomosis in 1 patient, a new stenosis distal to the previous anastomosis in 1, damage to the pedicle near the distal anastomosis during dissection of the IMA pedicle in 1, and the absence of suitable bypass conduits in 2 patients.

Surgical Technique

The sternum was opened with an oscillating saw, and the aorta and the right atrium were dissected free. The RIMA was harvested synchronously with the appropriate length of large saphenous vein if it was necessary and available. After adequate heparinization, the ascending aorta was cannulated, and a two-stage cannula was inserted into the right atrium for venous return. A left ventricular vent was inserted through the right superior pulmonary vein.

The patient was cooled to a core temperature of 30°C , and the used LIMA was carefully dissected, starting close to where it entered the pericardium. When it was possible to clamp the LIMA, the patient was cooled to a core temperature between 26° and 28°C , and slushed ice was used as topical cooling. When the heart fibrillated, the LIMA was clamped and infusion of cardioplegia started. Cold (4°C) St. Thomas' Hospital cardioplegia was delivered antegrade (3 patients) or retrograde (2 patients) through the coronary sinus coronarius cannula [4] until asystole occurred; cardioplegia was maintained by reinfusion of 100 mL/m^2 every 25 to 30 minutes or earlier if needed.

At the time of asystole, the LIMA-pedicle was further dissected. The distal anastomoses were done during a single period of aortic cross-clamping, and the proximal anastomoses were performed using a partial occluding clamp. Before the patient was weaned from extracorporeal circulation, he or she was rewarmed to a rectal temperature of 35°C , and hematocrit was increased to a minimum value of 0.24.

Results

The used LIMA was reimplanted into the LAD in 3 patients. In 1 of them, the stenotic anastomosis of the LIMA to the LAD was reconstructed. In the patient with

Accepted for publication May 29, 1992.

a new stenosis in the LAD just distal to the first LIMA-LAD anastomosis, the initial anastomosis was taken down, the incision in the LAD was extended over the new eccentric lesion, and a new LIMA-LAD anastomosis was constructed. The patient with a patent LIMA graft to the LAD received a RIMA graft to the first marginal branch and a venous graft side-to-side to the second marginal branch of the circumflex coronary artery ending on the distal right coronary artery. During the reoperation, a hematoma, probably resulting from the dissection, formed near the LIMA-LAD anastomosis and led to the need to reconstruct this anastomosis.

In 2 patients, there was a lack of good venous conduit material. One was a woman with extensive varicose veins. The patent LIMA-LAD graft was taken down, and the LIMA was anastomosed to the first and second marginal branches of the circumflex coronary artery. With the RIMA, a RIMA-LAD anastomosis was constructed. The RIMA in situ was not long enough to reach the circumflex coronary artery. In the last patient, adhesions prevented placement of the RIMA through the transverse sinus. The patent LIMA was used to construct a graft to the marginal branch of the circumflex coronary artery, the RIMA was used as graft to the LAD, and saphenous vein served as a graft to the distal right coronary artery. In these 2 patients, use of a free RIMA graft was rejected because of a thickened aorta.

Postoperatively there was no evidence of perioperative myocardial infarction. At follow-up ranging from 5 months to 4 years after reoperation, all patients are in New York Heart Association class I. Four patients had a negative treadmill test at the postoperative reevaluation. The fifth patient, a woman 70 years old, did not attend the reevaluation sessions. No control arteriograms were available because there was no medical indication for postoperative catheterization.

Comment

The number of reoperations for myocardial revascularization is increasing. Whereas the first reoperations were necessary because of progression of atherosclerosis in the native coronary system or an incomplete primary revascularization, graft failure and the combination of graft failure and progression of atherosclerosis are the most important angiographic indications for reoperation. Consequently, there are an increasing number of distal anastomoses at reoperation but a limited supply of suitable graft material.

In patients who received only venous grafts at the first operation, the rest of the saphenous vein as well as both IMAs are available at reoperation [2]. In more and more patients, however, the LIMA will be used as a graft to the LAD at the initial operation. Despite the superior patency rate of the IMA grafts and their good results in reducing angina [5], progression of atherosclerosis will occur in these patients in the native coronary system and venous grafts. In addition, widespread use of the IMA as a graft to relatively badly diseased coronary arteries will lead to a lower patency rate and an earlier return of angina. Use of

IMA grafts at the first operation leaves more large saphenous vein for reoperation, but in some patients, the usable saphenous vein in combination with the RIMA will not be sufficient for a complete revascularization.

Results with the use of upper extremity veins [6], allogenic veins [7, 8], and synthetic conduits [9] as graft material are disheartening, as are the results with the radial artery [10]. The use of the gastroepiploic artery and the epigastric artery as conduits in coronary reoperations has occasionally been reported but is not common [11]. Placing a free IMA graft during reoperations has been reported [2], but the anastomosis of the IMA to the thickened aorta can compromise patency, already lower than that of an in situ IMA graft [5]. An alternative is to redo the revascularization procedure and reuse the IMA graft in another place.

It is known that IMAs are nearly free from atherosclerosis and that there is a low incidence of atherosclerosis in IMA grafts over a long period [5, 12, 13]. At this time, there is no contraindication to the reuse of a patent IMA graft. Nevertheless, the takedown of a patent graft reflects an incomplete revascularization or a revascularization with inferior conduits.

Preoperative angiography of the used LIMA is essential to exclude stenoses in this graft, and it is helpful to have an idea of the position of the LIMA pedicle. This can be important for the dissection of the pedicle. Identification of the IMA pedicle is crucial; once the IMA pedicle is identified, further dissection to mobilize it is not a great problem. Dissection of the IMA pedicle is necessary because the IMA has to be clamped not only to ensure optimal myocardial protection by infusion of cardioplegia but also to manipulate the heart. Lack of good bypass conduits is a subjective indication, as every surgeon has his or her own ideas and criteria about what constitutes an inferior conduit. Nevertheless, with the evolution of the angiographic indications for reoperation and with the increasing number of repeat coronary reoperations [1], the lack of suitable graft conduits will be a problem in the future. Every reoperation will be a challenge where the creativity of the surgeon will be important.

Our initial experience with recycling of the LIMA graft is good. We reused the LIMA in 2 patients because there was a lack of good bypass conduits. In the other 3 patients, the indication for recycling the LIMA was not related to the absence of suitable bypass conduits (in 1 it was due to a perioperative injury), but their cases demonstrate that recycling an IMA graft is a possible alternative.

Notice From the Southern Thoracic Surgical Association

The Fortieth Annual Meeting of the Southern Thoracic Surgical Association will be held at Marriott's Bay Point Resort, Panama City Beach, Florida, November 4-6, 1993. The Postgraduate Course will be held the morning of Thursday, November 4, 1993, and will provide in-depth coverage of thoracic surgical topics selected primarily as a means to enhance and broaden the knowledge of practicing thoracic and cardiac surgeons.

Members wishing to participate in the Scientific Program should submit an original abstract and one copy by May 15, 1993, to Harvey I. Pass, MD, Program Chairman, Southern Thoracic Surgical Association, 401 North Michigan Avenue, Chicago, IL 60611-4267. Abstracts must be submitted on the Southern Thoracic Surgical Association abstract form. These forms may be obtained from the Association's office or in this issue of *The Annals of Thoracic*

Surgery. Manuscripts of accepted papers must be submitted to *The Annals of Thoracic Surgery* prior to the 1993 meeting or to the Secretary-Treasurer at the opening of the Scientific Session.

Applications for membership should be completed by July 1, 1993, and forwarded to Marion R. Lawler, MD, Membership Committee Chairman, Southern Thoracic Surgical Association, 401 North Michigan Avenue, Chicago, IL 60611-4267.

Anomalous Course of the Left Brachiocephalic Vein

Michael R. Mill, MD, Benson R. Wilcox, MD, Frank C. Detterbeck, MD, and Robert H. Anderson, MD

Division of Cardiothoracic Surgery, University of North Carolina School of Medicine, Chapel Hill, North Carolina; and Department of Paediatrics, National Heart and Lung Institute, Royal Brompton National Heart and Lung Hospitals, London, United Kingdom

An anomalous course of the left brachiocephalic vein beneath the aortic arch was identified in 7 patients undergoing surgical repair of congenital cardiac malformations. Six of these patients had the morphologic features of tetralogy of Fallot including severe obstruction to the right ventricular outflow tract and a right aortic arch. A review of the literature reveals this to be an uncommon anomaly. When it is present, however, it is frequently associated with a ventricular septal defect,

obstruction of the right ventricular outflow, and aortic arch anomalies. This anomaly can be documented by echocardiography, at cardiac catheterization, or intraoperatively. The presence of a subaortic left brachiocephalic vein may have implications for the conduct of surgical procedures, especially in the setting of tetralogy of Fallot.

(Ann Thorac Surg 1993;55:600-2)

Usually, the left brachiocephalic (innominate) vein courses anterior to the aortic arch and its brachiocephalic branches and joins the right brachiocephalic vein to form the superior caval vein (Fig 1). Rarely, the left brachiocephalic vein has an anomalous course beneath the aortic arch, where it then joins the superior caval vein between the azygos vein and the superior cavoatrial junction. Kershner [1] first described this anomaly in 1888, and it has been reported in the literature only occasionally since then. In this report we describe a series of patients diagnosed at the time of congenital heart operation, review the current literature, and comment on the potential clinical implications of this anomaly.

Patients and Methods

Seven patients undergoing repair of congenital cardiac malformations between September 1987 and June 1991 were found to have the left brachiocephalic vein coursing beneath the aortic arch at the time of operation. One patient was found to have a type B interrupted aortic arch with ductal continuity to the descending thoracic aorta. There was an anomalous origin of the right subclavian artery from the descending thoracic aorta just proximal to the left subclavian artery (Fig 2). In addition, this patient had an aortopulmonary window and an atrial septal defect within the oval fossa.

In the remaining 6 patients, the heart had the morphologic features of tetralogy of Fallot, and all of these had a right aortic arch (Fig 3). Five required a patch across the junction between the right ventricular outflow and the pulmonary trunk because of severe pulmonary stenosis. One patient had an adequately sized pulmonary valve and pulmonary trunk but required a patch confined to the right ventricular outflow tract. One patient had previ-

ously undergone placement of a left modified Blalock-Taussig shunt, and bilateral modified Blalock-Taussig shunts had been constructed in another patient before complete repair. Associated anomalies (Table 1) included one atrial septal defect within the oval fossa, one persistent left superior caval vein, and trisomy 21, and Cornelia-deLange syndrome in 1 patient each.

During this same period, 27 additional patients with tetralogy of Fallot underwent corrective operation. Twenty-one of these patients had a left aortic arch, whereas 6 had a right aortic arch. Seventeen required enlargement of the right ventricular outflow tract with a patch, and in 12 of these the patch extended across the ventriculopulmonary junction (the "annulus"). Two patients had a persistent left superior caval vein, in 1 of whom the left brachiocephalic vein was absent. In the remaining 26, the left brachiocephalic vein took its usual course.

Review

In the century after the initial description of this anomaly by Kershner [1], isolated cases have been reported. In 1985, Smallhorn and colleagues [2] analyzed 7 cases diagnosed by echocardiography. Gerlis and Ho [3] summarized these earlier reports in 1989 and added 3 autopsy cases of their own. Since then, others [4-6] have reported additional cases, all diagnosed by echocardiography. Together, as far as we are aware, a total of 58 cases have been documented, including the 7 cases in this report. Of these cases, only 8 were isolated anomalies with otherwise normal hearts, and all 8 were in male patients with left aortic arches.

In the 44 cases in which the sex of the patient is known, males outnumber females by a ratio of 2.1:1. Including only those cases with malformed hearts, the sex ratio is 1.6:1. The most frequently associated anomalies are those also commonly associated with tetralogy of Fallot, namely, right aortic arch, ventricular septal defect, and

Fig 1. Normal appearance of the left brachiocephalic vein.

obstruction of the right ventricular outflow tract. Of the 24 patients reported by Choi and associates [6], 20 had either tetralogy of Fallot, or pulmonary atresia in the setting of tetralogy. Of these 20 patients, 13 had right aortic arches, as did all 6 of our patients with tetralogy of Fallot. Other associated anomalies included common arterial trunk (2 patients), complete transposition (1 patient), interruption of the aortic arch (1 patient), and multiple complex anomalies (2 patients).

In the majority of cases, the subaortic brachiocephalic vein was noted to course anterior to the arterial ligament or a patent arterial duct. In a few cases, the brachiocephalic vein coursed either posterior to the ligament or behind the pulmonary trunk [3]. In all 7 of our patients, the left brachiocephalic vein coursed anterior to the arterial duct or its ligamentous vestige.

The exact incidence of this anomaly is unknown. Gerlis and Ho [3] estimated it to be 1 in 500 patients, based on the combined collections of approximately 2,000 hearts at their institutions and their review of previous case reports. Choi and associates [6] found an incidence of 1 in

Fig 3. Anomalous course of the left brachiocephalic vein in the patients with tetralogy of Fallot.

100 patients in their review of 2,457 echocardiograms of patients with congenital heart disease. Given the difference in methods used for diagnosis, an accurate determination of the prevalence is difficult. As there does not appear to be any pathophysiologic consequence of this anomaly, it may well go undetected in patients with otherwise normal hearts. It could also escape notice in the routine evaluation of patients with congenitally malformed hearts, thus leading to an underestimation of its true incidence.

Comment

Although of interest anatomically, the subaortic position of the left brachiocephalic vein is physiologically inconsequential. With echocardiography, it is most easily seen using suprasternal long-axis projections. Radiologically, the anomaly can be documented when catheters are placed in both the brachiocephalic vein and the aorta, or when contrast injection is made in the left brachiocephalic vein. Careful postmortem examination can also identify the anomaly.

The preoperative diagnosis of this anomaly should prompt a thorough search for the presence of obstruction

Fig 2. Anomalous course of the left brachiocephalic vein in the patient with type B interrupted aortic arch (patient 1).

Table 1. Patient Characteristics

Patient	Age ^a	Sex	Diagnosis	Associated Anomalies
1	3 days	M	IAA	APW/ASD
2	50 mo	F	TOF	R aortic arch/PFO
3	6 mo	F	TOF	R aortic arch/ASD/LSVC
4	24 mo	M	TOF	R aortic arch/Cornelia-deLange syndrome
5	19 mo	F	TOF	R aortic arch/trisomy 21
6	55 mo	M	TCF	R aortic arch/PFO
7	24 mo	M	TCF	R aortic arch

^a Age at time of operation.

APW = aortopulmonary window; ASD = atrial septal defect; IAA = interrupted aortic arch; LSVC = left superior caval vein; PFO = patent foramen ovale; R = right; TOF = tetralogy of Fallot.

Fig 4. Connection of the anomalous brachiocephalic vein at the superior cavoatrial junction.

within the right ventricular outflow tract, a ventricular septal defect, and a right aortic arch. Conversely, when the diagnosis is made of tetralogy of Fallot with pulmonary stenosis or atresia, the anomalous position of the left brachiocephalic vein beneath the aortic arch should be considered, especially in those patients with a right aortic arch. Recognition of this anomaly may avoid its confusion with the presence or absence of central pulmonary arteries in pulmonary atresia, or a venous confluence in totally anomalous pulmonary venous connection [3].

We identified this entity at the time of median sternotomy for the repair of congenital heart lesions. Its identification has several important implications. Upon initial exploration through a median sternotomy, one might mistakenly conclude that the left brachiocephalic vein is absent. This would suggest the presence of a persistent left superior caval vein, which carries implications for the establishment of adequate venous drainage in the circuit used for cardiopulmonary bypass. Of course, with a subaortic brachiocephalic vein, additional cannulation of the left superior caval vein is not necessary. Because of the anomalous entry of this vein at the superior cavoatrial junction (Fig 4) as opposed to the normal more distal connection, the use of direct cannulation of the superior caval vein must be done with extreme care to avoid obstruction of the left brachiocephalic vein by the venous cannula or damage to the adjacent sinus node or its blood supply. Another situation in which this anomaly might affect surgical technique is in the construction of a bidirectional Glenn shunt as part of a Fontan-type procedure. When performing systemic-to-pulmonary anastomoses,

the presence of this anomaly may also complicate exposure of the pulmonary arteries. Finally, a subaortic left brachiocephalic vein may complicate the exposure and ligation of a patent arterial duct.

Noteworthy is the fact that all 6 patients in this series with tetralogy of Fallot and an anomalous left brachiocephalic vein had a right aortic arch, whereas only 6 of 27 patients (22%) without the anomalous vein had a right aortic arch. This latter percentage is consistent with the accepted incidence of right aortic arch in tetralogy of Fallot of 25% [7].

Of particular interest in these patients with tetralogy of Fallot is the high incidence of relatively severe obstruction in the right ventricular outflow tract. All 6 patients were found to require enlargement of the outflow tract, with patches across the ventriculopulmonary junction in 5. This is in contrast to the finding that 17 of the 27 patients (63%) without the anomalous left brachiocephalic vein required placement of a patch in the outflow tract, with only 12 of these crossing the ventriculopulmonary junction. This anomaly thus appears to be associated with a greater degree of obstruction in the right ventricular outflow tract, and its presence should alert the surgeon to the possible need for a more extensive procedure to accomplish a satisfactory repair. Although this systemic venous anomaly is relatively uncommon, knowledge of it has potentially important implications in the surgical care of patients with congenitally malformed hearts, especially in the setting of tetralogy of Fallot.

Primary Repair of Iatrogenic Thoracic Esophageal Perforation and Boerhaave's Syndrome

Sunil K. Ohri, FRCS, Theodore A. Liakakos, MD, Vivek Pathi, FRCS, Edward R. Townsend, FRCS, and S. William Fountain, FRCS

Department of Thoracic Surgery, Harefield Hospital, Harefield, Middlesex, United Kingdom

Ten patients seen at our unit over a 24-month period with either iatrogenic ($n = 5$) or spontaneous thoracic esophageal perforations ($n = 5$) were retrospectively reviewed. Five patients were seen within 24 hours of onset of symptoms, and 5 were seen after 24 hours or later. There was no significant difference in the presentation or subsequent clinical course in patients seen less or more than 24 hours after the onset of symptoms. Nine patients underwent primary repair together with drainage of the mediastinum, and in 1 of these a Heller's myotomy was also performed for achalasia. One patient had a two-stage esophagogastrectomy for a benign esophageal stricture. One patient (10%) with a spontaneous perforation died 48 hours after operation and was found at postmortem examination to have an in situ carcinoma at the site

of the perforation. Four patients (40%) had nonfatal complications. Fistulas developed in 3 patients (30%); in 1 of these patients a second thoracotomy and a further rib resection was required for drainage of a mediastinal abscess. An esophagocutaneous fistula and a persistent mediastinal abscess developed in 1 patient (10%) and necessitated two further thoracotomies for effective drainage. The mean hospital stay was 38.4 ± 25.4 days (range, 16 to 76 days). The findings of this study suggest that primary repair combined with a drainage procedure is the treatment of choice for patients with a perforated intrathoracic esophagus, including those seen more than 24 hours after the onset of symptoms.

(*Ann Thorac Surg* 1993;55:603-6)

Despite advances in the treatment of esophageal perforations over the last three decades, the mortality remains high [1, 2]. The anatomical location of the esophagus predisposes the patient to the development of fatal mediastinitis and multisystem organ failure if the perforation remains unrecognized. The diagnosis may be delayed because esophageal perforation may masquerade as many other clinical disorders [3]. Boerhaave's syndrome has the highest surgical mortality [4], and this has been related to the barogenic nature of the rupture with wider mediastinal and pleural contamination.

Over recent years, we have adopted a more aggressive surgical policy for the management of iatrogenic perforations for benign disease and Boerhaave's syndrome. We present our results over a 24-month period for 10 consecutive esophageal perforations.

Patients and Methods

The hospital charts of 10 patients treated for esophageal perforation after instrumentation or occurring spontaneously between July 1989 and July 1991 were reviewed. Patients who had perforation with known malignancies were excluded, because the management of malignant perforations has been previously reported by us [5]. The preoperative and postoperative courses were analyzed

and factors identified that contributed to morbidity or mortality.

When first seen all patients were resuscitated by insertion of a central venous line and commenced on a regimen of intravenous antibiotics (cefotaxime, metronidazole, and ampicillin) and fluid. A barium swallow was performed in all patients on arrival to our unit, unless performed by the referring center.

Table 1 provides the clinical details of 10 patients; 5 patients had iatrogenic perforations and 5 perforations occurred spontaneously. In 4 patients who underwent esophagoscopy, the investigation was for dysphagia. One of these patients (patient 9) had a long history (10 years) of dysphagia, and from previous investigations was known to have a benign stricture at 25 cm. Because of her chronic history of dysphagia, when an iatrogenic perforation occurred during esophagoscopy under general anesthesia, an Ivor-Lewis two-stage esophagogastrectomy was performed rather than simple closure. Subsequent histologic examination of the resected specimen found an esophageal ulcer with pseudoepitheliomatous hyperplasia and proliferation of the squamous epithelium. Another patient in this group had achalasia and underwent a Heller's myotomy.

All the patients with Boerhaave's syndrome had typical presentation with a history of vomiting after eating a meal except for patient 4, whose perforation appeared to be completely painless and without a history of vomiting. One patient in the spontaneous group (patient 10) was thought to clinically have Boerhaave's syndrome, but

Table 1. Clinical Features and Management of Patients With Iatrogenic Perforations of the Esophagus and Boerhaave's Syndrome

Patient No.	Age (y)	Type of Perforation	Delay to Presentation (h)	Time from Perforation to Operation (h)	Operative Treatment	Outcome
1	55	Iatrogenic: esophagoscopy & dilation	14	22	T & L, G & J	Alive
2	58	Boerhaave	8	14	T & L, G & J	Alive
3	58	Iatrogenic: esophagoscopy & dilation for achalasia	4	31	T & L, G & J, & Heller's myotomy	Alive
4	75	Boerhaave	6.5	12	T & L, G & J	Alive
5	57	Iatrogenic: esophagoscopy & dilation	Immediate	24	T & L, G & J	Alive
6	83	Boerhaave	12	18	T & L, G & J	Alive
7	64	Iatrogenic: esophagoscopy & dilation	72	94	Left thoracotomy, G & J	Alive
8	77	Spontaneous perforation	48	60	T & L, G & J	Died 48 hours postop of septicemia
9	74	Iatrogenic: esophagoscopy & dilation of benign stricture (10-year history of dysphagia)	Nil: during general anesthesia for esophagoscopy	Proceeded to esophagectomy	Two-stage esophagogastrrectomy & J	Alive
10	60	Iatrogenic: esophagoscopy & dilation	12	24	T & L, G & J	Alive

G = drainage gastrostomy; J = feeding jejunostomy; L = mini-laparotomy; T = thoracotomy.

histologic examination of the autopsy specimen found an in situ carcinoma on the edge of the esophageal perforation.

The time delay from the onset of symptoms to arrival at the hospital varied from 0 to 72 hours (mean, 17.7 ± 23.5 hours), but the time from symptoms to operation was 0 to 94 hours (mean, 29.9 ± 27.4 hours), with 5 patients receiving operation at 24 hours or more after the onset of symptoms.

Thoracotomy with oversew of the esophageal perforation with interrupted single-layer polyglactin together with mediastinal drainage was performed in 8 patients. In patient 3 (see Table 1), a Heller's myotomy was also performed at the same time as esophageal repair, because a preperforation diagnosis of achalasia had been made. As outlined above, 1 patient had a two-stage esophagogastrrectomy for iatrogenic perforation of the esophagus after dilation for a benign stricture. All patients underwent a mini-laparotomy for the insertion of a drainage gastrostomy and feeding jejunostomy.

A Gastrografin (Schering Health Care, Burgess Hill, UK) radiocontrast swallow was routinely performed on day 5 postoperatively. If this study was negative for an anastomotic leak, the gastrostomy tube was removed and oral administration of fluids commenced. The jejunostomy tube was clamped off but left in situ for a further 24 hours. At the end of this period, if the patient had

successfully proceeded to a soft diet the jejunostomy feeding tube was also removed. Both the gastrostomy and jejunostomy wounds were allowed to heal by secondary intention. However, in the presence of an anastomotic leak, the gastrostomy and jejunostomy tubes were left in situ for continued gastric diversion and jejunostomy feeding until a repeat radiocontrast swallow could no longer demonstrate anastomotic leakage; this was necessary in 3 of our patients.

Results

The presenting features of the patients with subsequent complications in the intensive care unit are provided in Table 2. No significant difference was found in the presenting features of patients who were seen less than or greater than 24 hours from the onset of symptoms. Seven of the 10 patients were already receiving intravenous broad-spectrum antibiotics at the time of arrival to our unit, and 6 of these patients had metronidazole as part of their antibiotic regimen. The early institution of antibiotics and the use of an antianaerobe may have facilitated the low mortality in our group of patients. There was no significant difference in the intensive care unit course of patients who presented less than or greater than 24 hours after onset of symptoms. The ventilation time for patients in intensive care unit was 0.3 to 7 days (mean, 1.1 ± 2.1

Table 2. Presentation and Intensive Care Unit Complications

* Patients seen 24 hours or later after the onset of symptoms.

ICU = intensive care unit.

days). In 1 patient, who was ventilated for 7 days, adult respiratory distress syndrome developed after operation.

After operation persistent leaks demonstrable on Gastrografin swallow developed in 3 patients. In 2 patients leaks were successfully managed by prolonged jejunostomy tube feeding. However, 1 patient required a second thoracotomy for drainage of a paraesophageal abscess. A rib resection was also necessary in the same patient to drain a mediastinal abscess. A persistent esophagocutaneous fistula in this man (patient 4) was successfully healed by endoscopic application of sodium hydroxide to the esophageal ostium of the fistulous tract. A fourth patient without a demonstrable radiological leak required a second thoracotomy for drainage of a mediastinal abscess.

One patient (patient 8) died in this series. She was seen late (60 hours) after the onset of her symptoms and was undergoing therapy with azathioprine and corticosteroids for bullous pemphigoid. Despite the early institution of antibiotic therapy septicemia developed and she died 48 hours after operation. An autopsy found a gangrenous esophagus and necrotizing mediastinitis, with an in situ carcinoma at the edge of the perforation that had not been detected on macroscopic inspection at the time of thoracotomy.

From Table 1 it may be noted that the time from presentation to operation was protracted in some cases, eg, for patient 3 this was 27 hours. This reflects our position as a referral center for these patients. The delay to operation was due to a combination of time taken in establishing the diagnosis at the referring hospital together with time required for transportation of the patient to our unit.

The mean hospital stay was 38.4 ± 25.4 days (range, 16 to 76 days). At discharge all the patients were on a normal

diet without dysphagia. Follow-up was at 6 weeks in an outpatient clinic, at which time 8 of the 9 patients remained well and were discharged; 1 patient was lost to follow-up.

Comment

The management of esophageal perforations remains unclear in the literature because of the heterogeneity of causes and management strategies of reported cases. We have employed a similar technique in 9 of 10 cases presented. In 1 case, esophageal resection was undertaken because of the presence of a benign esophageal stricture. The remaining patients were treated by primary oversew of the perforation and a drainage gastrostomy, except for 1 patient, who also had a Heller's myotomy for achalasia. A feeding jejunostomy was inserted in all patients at the time of primary esophageal repair. This is useful in the postoperative period when prolonged feeding becomes necessary; 2 patients with esophageal leaks were successfully managed by jejunostomy feeding until the leak closed.

It has been suggested that primary closure of the perforation with mediastinal drainage should be reserved for patients seen within 24 hours [6, 7]. Flynn and associates [7] recommended nonoperative treatment for late-presenting perforations, because of infected tissues, which in their view precluded a definitive operation. Although interventional radiological techniques may allow the insertion of a drainage tube through the naso-esophageal, gastroesophageal, or transpleural route [8], this requires radiological expertise, and may still put the patient at risk from a subsequent mediastinal abscess. The alternatives to repair of the perforation are conservative or medical therapy [9], or one of the many drainage or diversion techniques [10-14]. The mortality in a collected series of 80 patients in whom the drainage/diversion technique was used was 35.5% [15], compared with a mortality of 25% for simple repair in a collected series of 158 patients [15]. This latter mortality is an overall mortality; patients with cervical esophageal perforations have a better prognosis [6], whereas those seen late (>24 hours) have a poorer prognosis. Patients with Boerhaave's syndrome in particular have a high mortality of 25% [4], which may be due to the explosive nature of the perforation resulting in wider mediastinal contamination and rapid onset of necrotizing mediastinitis. The 1 patient who died in our study was seen late (48 hours) with spontaneous perforation, but was subsequently found at autopsy to have an in situ carcinoma at the esophageal tear.

The reported frequency of leaks after simple closure after 24 hours is approximately 50% [16-18], with a 39% incidence of fistulas in a collected series of 158 patients [15]. A number of autogenous tissue flaps have been described over recent years to reinforce the repaired esophageal tear [19-21]. Richardson and associates [22] in 1985, reported excellent results with the use of a muscle flap in a small group of 5 patients. The most widely employed technique has been the pleural flap described

by Grillo and Wilkins [21]. In a series of 14 patients, Gouge and associates [15] reported two leaks (14%) but no fistulas. These authors recommended the employment of a buttressing flap in all cases of primary repair. This was supported by the finding of a 13% incidence of fistulas in a collected series of 99 patients who received a number of different buttressing techniques. In our series only one fistula (10%) developed. The low incidence of complications and high survival rate in our series may be due to the high throughput of such cases in our unit. The 10 cases we have reported were seen over a 24-month period, whereas Gouge and associates [15] reported on 14 patients with the Grillo flap treated over 13 years.

Esophagectomy is indicated when underlying esophageal disease may be expected to prevent successful healing of the perforation. At the time of thoracotomy this was missed in 1 of our patients, who subsequently died, but in another patient this was successfully performed because of a benign stricture. We have reported a 36.3% mortality for esophageal resection for perforated esophageal malignancies, whereas all 4 patients who had resections for benign perforations survived [5]. Transhiatal esophagectomy has been recommended for malignant perforations [23, 24]. Yeo and associates [24] performed four transhiatal esophagectomies with cervical esophagostomy without any mortality.

Perforation of the intrathoracic esophagus is a life-threatening condition, and delay in diagnosis and therapy remains a major contributor to the attendant mortality. Few patients fulfill the criteria of Cameron and associates [9] for conservative therapy, ie, the perforation must be contained, the cavity must drain back into the esophagus, and there must be no evidence of sepsis. Drainage or diversion therapy is associated with an unacceptably high morbidity and mortality. Primary repair with a drainage procedure is the treatment of choice in all patients, including those seen more than 24 hours after the onset of symptoms. The use of autogenous tissue buttressing remains controversial. However, the use of the latter technique or indeed the management of this lethal condition is not for the occasional esophageal surgeon. We would recommend referral of patients with esophageal perforations to centers with experience in the management of this condition.

Cox/Maze Procedure for Atrial Septal Defect With Atrial Fibrillation: Management Strategies

Lawrence I. Bonchek, MD, Mark W. Burlingame, MD, Seth J. Worley, MD, Brad E. Vazales, MD, and Edward F. Lundy, MD, PhD

Lancaster General Hospital, Lancaster, Pennsylvania

Atrial fibrillation is found at late follow-up in approximately half of all adults who have had correction of atrial septal defect, even if it was not present preoperatively. These patients are thus exposed to the risks of stroke and chronic drug therapy even after a successful operation. Simultaneous surgical correction of atrial septal defect

and atrial fibrillation was accomplished in a 52-year-old man by means of the Cox/maze procedure. The small added risk and the substantial benefit of eliminating atrial fibrillation suggest that this approach is warranted in selected adults with atrial septal defect.

(Ann Thorac Surg 1993;55:607-10)

Atrial septal defect is the third most common form of congenital heart disease in adults (only bicuspid aortic valve and mitral valve prolapse are more common), and it is frequently associated with atrial fibrillation or flutter [1]. Although the incidence of atrial fibrillation increases with age even in the general population, and ranges from 3.7% of patients older than 65 years to 11.6% of those older than 75 years [2-4], the incidence in patients with atrial septal defect is strikingly higher even after surgical closure [5-7]. In a recent review from the Mayo Clinic of late results 27 to 32 years after surgical repair of isolated atrial septal defect, patients who had closure of an atrial septal defect after age 41 years had a 59% chance of having atrial fibrillation or flutter at late follow-up [1]. For patients who had atrial septal defect closure between the ages of 25 and 41 years, the incidence of late atrial fibrillation or flutter was still 41%, even though only 6% had those arrhythmias preoperatively.

For editorial comment, see page 578.

Several recent studies have demonstrated that atrial fibrillation imposes substantial risks of stroke or death [8-10]. In patients with nonrheumatic atrial fibrillation in the Framingham study [9], the risk ratio for stroke was 5.6 compared with patients without atrial fibrillation, even after adjusting for age and blood pressure. During a 20-year follow-up period, patients in whom atrial fibrillation developed were twice as likely to die as those in whom it did not. This increased risk was attributed in part to their associated heart disease, but also to the excess risk of stroke. In the Mayo Clinic study of atrial septal defects [1], even patients who had closure of an atrial septal defect between the ages of 25 and 41 years had shortened life spans, and those with closure after age 41 years had

an even greater increase in late mortality. Of 35 late cardiac events in the cohort older than 24 years at closure, eight events were strokes and two were transient ischemic attacks.

In patients with normal cardiac function, atrial fibrillation is generally assumed to be well tolerated, but even in those patients there are hazards besides the well-known risks of thromboembolism and anticoagulation. Prospective echocardiographic studies indicate that atrial fibrillation alone can cause left atrial enlargement [11]. A rapid ventricular rate, as may be present in poorly controlled atrial fibrillation, can cause tachycardic cardiomyopathy [12]. Calcium-channel-blocking drugs, which are often used to control the ventricular response in atrial fibrillation, can exacerbate heart failure [13]. Finally, the antiarrhythmic drugs that are used in an effort to prevent atrial fibrillation have well-recognized proarrhythmic effects. Long-term antiarrhythmic therapy increases mortality substantially, even with familiar drugs such as quinidine [14].

A surgical procedure to abolish atrial fibrillation and flutter has been described by Cox [15, 16]. It therefore seemed to us that in selected adult patients it would be beneficial to surgically correct atrial fibrillation simultaneously with closure of isolated atrial septal defects. Several precisely located incisions are made in the atria and then are closed, creating a maze in which the propagating electrical wave fronts are extinguished at the suture lines (Fig 1). The reentrant circuits that maintain atrial fibrillation cannot be sustained because of the electrical refractoriness that follows the propagating wavefronts through the maze. Closure of a secundum atrial septal defect is readily incorporated into the operation, because the standard Cox/maze procedure includes an incision in the atrial septum to interrupt conduction across the fossa ovalis. In patients with a secundum atrial septal defect, the usual septal incision of the Cox/maze procedure is eliminated, and the atrial septal defect is closed with a patch.

Fig 1. The incisions used for the Cox/maze procedure are displayed in two dimensions (a, b) and three dimensions (c). Propagating electrical wavefronts (black arrows) are extinguished at the suture lines. In the upper left and lower panels, the heart is seen from the posterior view. Incisions A-A' and E-C' depict amputation of the right and left atrial appendages, respectively. (Reproduced from Cox JL, Schuessler RB, Agostino HJ, et al. The surgical treatment of atrial fibrillation: III. Development of a definitive surgical procedure. *J Thorac Cardiovasc Surg* 1991;101:569-83, by permission of Mosby-Year Book, Inc.)

Case History

A 52-year-old man in good general health noted a dry cough, occasional shortness of breath, and episodes of palpitations that increased in frequency, severity, and duration. Evaluation revealed a secundum atrial septal defect with a pulmonary/systemic flow ratio of 2.5:1 and normal pulmonary artery pressure. Atrial fibrillation/flutter alternated with intervals of sinus rhythm. He was referred for surgical closure of his atrial septal defect. After extensive discussions of the risk of simple closure of his atrial septal defect, the risks of atrial fibrillation even

after successful closure of his atrial septal defect, and the risks of the Cox/maze procedure, he elected to undergo the combined procedure.

The Cox/maze procedure was performed uneventfully on July 31, 1991, and the atrial septal defect was closed with a patch of autologous pericardium. The postoperative period was entirely uneventful. Inotropic drugs were not used and blood transfusion was unnecessary. Atrial fibrillation was never observed postoperatively. A visible P wave was noted on the electrocardiogram within 24 hours after operation, with a 1:1 ventricular response.

During the first postoperative week the predominant rhythm was sinus, with long periods of junctional rhythm. (In Cox's patients, junctional rhythm has also predominated early after operation.) A postoperative echocardiogram confirmed closure of the atrial septal defect and contraction of the atria. The patient was anticoagulated for 6 weeks while atrial suture lines healed, and administration of anticoagulants was then stopped. He returned to work as a commercial photographer within 6 weeks. One year postoperatively he remains in sinus rhythm receiving no medications and is asymptomatic.

Comment

Cox has demonstrated the efficacy and safety of the operative procedure he devised for atrial fibrillation. Twenty-six patients have had successful Cox/maze procedures with no deaths (Cox JL; personal communication). The procedure is indeed considerably more intricate and prolonged than simple closure of an atrial septal defect, and requires experience with cryosurgical techniques as well. Cryolesions must be placed wherever macroreentry circuits could propagate along structures that cannot be surgically interrupted: the mitral and tricuspid annuli and the coronary sinus. Nonetheless, although the precise operative risk cannot yet be quantitated, it should be quite low (<2%) in the hands of experienced surgeons, because the operation is confined to the atria, and ventricular function is not affected if proper intraoperative myocardial protection is provided. As the entire procedure is done through the atria, the ventricle can be kept cold within a cooling jacket throughout the period of myocardial ischemia [15, 17]. Our patient did not require any inotropic support postoperatively.

Although catheter techniques for closure of atrial septal defects now show more promise than in the past, long-term follow-up is not yet available, and the technique is suitable only for small to medium defects [18, 19]. It is unlikely that catheter closure will alter the late incidence of atrial fibrillation in patients with an atrial septal defect that becomes manifest in adult life.

Even now, when experience with the Cox/maze procedure is still limited, it seems acceptable to us to consider adding the Cox/maze procedure to routine surgical closure of an atrial septal defect in certain subsets of adult patients. For patients older than 40 years, the likelihood is greater than 50% that atrial fibrillation will develop or be maintained postoperatively [1]. Patients older than 25 years have more than a 40% chance of development of atrial fibrillation. Such patients will require life-long drugs to control their heart rate and rhythm, with the inevitable adverse effects discussed earlier. Patients with atrial fibrillation will also require anticoagulation with warfarin because warfarin markedly reduces their risk of stroke [8, 20, 21].

We therefore propose that the following management guidelines might be considered for adults with atrial septal defect: (1) Patients younger than 25 years with small to medium-sized defects and no arrhythmias should

be considered for catheter closure if the early auspicious reports are confirmed by further experience and late follow-up. (2) Patients younger than 25 years with large defects and no arrhythmias should have surgical closure alone, because the operative risk is negligible and information about late arrhythmias is insufficient to justify a more complex operation with higher risk. (3) Patients older than 40 years with atrial septal defects large enough to require closure, and patients with atrial septal defects and atrial fibrillation/flutter at any age beyond childhood, should have surgical closure and—in experienced centers—consideration of the Cox/maze procedure. This recommendation would not be made in the presence of clinical factors that substantially increase operative risk, such as valvular heart disease or renal failure. (4) Adult patients between the ages of 25 and 40 years with small to medium-sized defects and no arrhythmias can be considered for catheter closure or surgical closure. Surgical closure combined with the Cox/maze procedure may in the future prove to be an appropriate strategy, but at present we lack sufficient information about the risks and long-term benefits of the combined approach in this subset of patients.

In adult patients with atrial septal defects large enough to require operation anyway, the Cox/maze procedure will add a small increment of risk that should be more than counterbalanced by a large benefit. It may also be mentioned parenthetically that there are other circumstances in which atrial fibrillation alone may be an indication for operation [16]. Furthermore, as experience with the Cox/maze procedure increases, and it is done with more certainty and speed, it will surely be combined with more extensive cardiac procedures such as mitral valve reconstruction or replacement in patients with chronic atrial fibrillation and mitral valve disease. Cox has already carried out those combined procedures (Cox JL; personal communication).

We recognize that these proposals require discussion and debate. Many surgeons may disagree on the grounds that these management guidelines are premature and inadequately substantiated. We wish only to document our successful case in the hope that it will provoke consideration of the Cox/maze procedure for patients who might otherwise not benefit from that operation.

Technique for Resecting Primary and Metastatic Nonbronchogenic Tumors of the Thoracic Outlet

Paolo Macchiarini, MD, Philippe Darteville, MD, Alain Chapelier, MD, Bernard Lenot, MD, Jacques Cerrina, MD, François Le Roy Ladurie, MD, and François Parquin, MD

Department of Thoracic and Vascular Surgery and Heart-Lung Transplantation, Hôpital Marie-Lannelongue (Paris-Sud University), Plessis Robinson, France

Although primary or metastatic nonbronchogenic tumors infrequently arise in or involve the thoracic outlet, they represent a major surgical challenge because of their tendency to encapsulate outlet structures. Fourteen patients with a histologically proven primary ($n = 8$) or metastatic ($n = 6$) nonbronchogenic outlet tumor were treated by an anterior transcervical approach, including an L-shaped cervicotomy extended into the deltopectoral groove, resection of the internal half of the clavicle, and, in the case of tumor involvement, resection of the jugular and subclavian veins, phrenic nerve, subclavian artery, brachial plexus, and ribs. All patients underwent a radical resection. Tumors extended to bony (usually the first rib), muscular (usually the anterior scalenus muscle), and nerve (usually the phrenic nerve) outlet structures in 8, 10, and 7 patients, respectively. Ten patients had involvement of outlet vessels: 6 had simple ligation ($n = 5$) or wedge resection ($n = 1$) of the subclavian vein

and related branches, 1 had revascularization of both the subclavian vein by an end-to-end anastomosis and the subclavian artery by a ringed polytetrafluoroethylene graft, 1 had revascularization of the subclavian artery alone, and 2 had revascularization between the left brachiocephalic vein and superior vena cava (ringed polytetrafluoroethylene graft). Follow-up venograms showed complete patency of the anastomoses. There was one postoperative death (7%) due to multiorgan system failure. Other complications were mild and short-lasting. With a median follow-up of 3.4 years, all patients but 1 (who had systemic progression) are alive and disease free 3 to 127 months postoperatively. Radical resection of primary or metastatic nonbronchogenic outlet tumors and encouraging long-term survival can be achieved using the technique presented.

(*Ann Thorac Surg* 1993;55:611-8)

During the last two decades, the surgical approach to the anterior aspect of the median cervicothoracic junction has been carefully delineated. As a result, surgical procedures for benign and malignant diseases involving the cervical trachea [1], esophagus [2], or both [3, 4] are usually associated with excellent results and low morbidity and mortality. In contrast, the surgical management of neurovascular disorders and malignant diseases involving the thoracic outlet is less well codified, and although various posterior and anterior approaches have been reported, none of them has been widely accepted [5, 6]. This is because the surgical manipulation of structures such as the subclavian artery and vein, phrenic nerve, and brachial plexus is very hazardous and carries a high risk of devastating complications.

Primary and metastatic nonbronchogenic outlet tumors are uncommon neoplasms that may arise from any of the histological elements of this target area. They usually display an aggressive local behavior in that they are deeply infiltrative, and they have a propensity for local

recurrence [7, 8]. Although wide and conservative surgical excision offers the best hope for cure, the frequent encapsulation of outlet structures raises the risk of major injuries, thereby precluding a radical operation. We [9] previously documented the technical feasibility and efficacy of obtaining radical resection of bronchogenic tumors involving extensively the structures of the thoracic inlet by an anterior transcervical approach. Here we present our anecdotal experience with this approach for primary and metastatic nonbronchogenic outlet tumors.

Material and Methods

Between April 1981 and January 1992, 14 patients (6 male and 8 female) with a median age of 44 years (range, 3 to 66 years) with a histologically proven primary ($n = 8$) or metastatic ($n = 6$) nonbronchogenic outlet neoplasm were referred to our institution. Their preoperative demographic profile is shown in Table 1. The primary tumors included 1 Ewing's sarcoma of the first rib, 2 neurofibromas (schwannomas), 2 low-grade fibrosarcomas, 1 fibroma, and 2 radiation-induced fibrosarcomas. The metastatic lesions originated from 1 malignant melanoma of unknown origin, 1 ovarian cancer, 1 testicular teratoma, 1 thyroid cancer, 1 esophageal cancer, and 1 adenocarcinoma of unknown origin. Both radiation-induced fibro-

Table 1. Demographic Profile

Patient No.	Sex	Age (y)	Tumor Origin	Tumor Type	Tumor Extension	Side	Signs and Symptoms	Preoperative Diagnosis	Previous Local Treatment
1	F	27	Primary	Anterior	Thoracic outlet, mediastinum axilla	Left	Local mass	Schwannoma ^a	Incomplete resection
2	F	59	Primary	Posterior	Thoracic outlet, intraspinal extension (T3-4)	Left	Horner's syndrome	Schwannoma	None
3	F	21	Primary	Posterior	Thoracic outlet, intrathoracic extension	Right	Cervical mass, pain, upper limb edema	Low-grade fibrosarcoma	Multiple incomplete resections, RT (60 Gy)
4	F	50	Primary	Posterior	Thoracic outlet, subscapular fossa	Right	Pain in neck, upper chest and outer arm, venous distention	Low-grade fibrosarcoma	Multiple resections, RT (60 Gy)
5	M	39	Metastatic	Anterior	Thoracic outlet	Left	Local pain	Melanoma of unknown origin	Multiple resections
6	F	24	Primary	Anterior	Thoracic outlet	Left	Shoulder pain, cyanosis and edema of upper limb, phrenic nerve palsy	Ewing's sarcoma of 1st rib	None
7	F	48	Metastatic	Anterior	Thoracic outlet	Left	Local pain, venous distention	Metastatic ovarian cancer	Incomplete resection, RT (17 Gy), and CT
8	M	28	Metastatic	Anterior	Thoracic outlet	Left	Local pain	Metastatic teratoma from carcinoma of testes	None
9	M	40	Metastatic	Anterior	Thoracic outlet, 1st & 2nd ribs	Right	Pain and paresthesia in C8-T1 root	Adenocarcinoma of unknown origin	None
10	F	66	Primary	Anterior	Thoracic outlet	Right	Pain and paresthesia in C8-T1 root, upper limb edema	RIF (breast cancer operation and RT)	None
11	M	3	Primary	Middle	Thoracic outlet, scapula	Right	Local pain	Fibroma	None
12	M	56	Metastatic	Anterior	Thoracic outlet, 1st and 2nd ribs	Right	Local pain	Thyroid carcinoma	Local resection
13	M	52	Metastatic	Anterior	Thoracic outlet	Right	Upper limb edema	Esophageal cancer	None
14	F	57	Primary	Anterior	Thoracic outlet, clavicle, manubrium, and 1st and 2nd ribs	Right	Local pain	RIF (breast cancer operation and RT)	Claviclectomy, manubrial resection

^a In this patient, schwannoma was associated with von Recklinghausen's disease.

CT = cytotoxic chemotherapy; RIF = radiation-induced fibrosarcoma; RT = radiation therapy.

sarcomas occurred at the margin of the radiation field and were of different histologic type than the original tumor (breast cancer). Seven patients (50%) had undergone unsuccessful surgical attempts to remove the tumor before referral, and among these, 2 and 4 patients were experiencing the second and third local recurrence, respectively.

Preoperative Staging

Preoperative staging included history and physical examination, biochemical profile, chest roentgenography, bronchoscopy, computed tomography of the chest, abdominal ultrasound, bone scan, and cardiopulmonary tests. Neurologic examination, electromyography, and fluoroscopy were done to delineate involvement of the brachial plexus and phrenic nerve by the tumor. Vascular invasion was studied with venous angiography, subclavian arteriography, Doppler ultrasonography, and magnetic resonance imaging.

Anatomic Classification

Based on their anatomic location, outlet tumors were classified as anterior (tumor invading the anterior part of the first rib, sternum, manubrium, subclavian vessels, anterior scalenus muscle, and phrenic nerve), middle (tumor involving the middle part of the first rib and extending high into the middle scalenus muscle), and posterior (tumor located close to the vertebral body and invading the posterior part of the first rib, the lower roots of the brachial plexus, the posterior wall, and branches of the subclavian artery).

Surgical Technique

The surgical technique has been extensively detailed elsewhere [9]. Briefly, one-lung anesthesia with measurement of central venous and arterial pressures and body temperature is necessary. A Foley catheter is inserted. The patient is placed in the supine position with the neck hyperextended and the head turned away from the involved side. An L-shaped cervicotomy is made; the vertical and horizontal branches follow the anterior border of the sternocleidomastoid muscle and the inferior border of the internal half of the clavicle, respectively (Fig 1). Division of the sternal attachment of the sternocleidomastoid muscle allows good exposure of the superior border of the subclavian vessels and permits assessment of the extent and resectability of the tumor. The internal half of the clavicle is removed.

The operative procedure is carried out in three steps: primary dissection of the veins, dissection of the arteries, and exposure of the brachial plexus. The jugular and subclavian veins are dissected first so that branches to the subclavian vein can eventually be divided. On the left side, ligation of the thoracic duct is usually required. Division of the distal part of the jugular vein makes the approach to the venous confluence at the origin of the innominate vein easier. If the subclavian vein is involved by tumor, it can easily be resected after proximal and distal control has been achieved. Direct extension of the tumor to the innominate vein does not preclude resection.

Fig 1. Left transcervical incision: The patient is placed in the supine position with the neck hyperextended and the head turned away from the involved side. An L-shaped skin incision is made from the angle of the mandible down to the sternal notch, extended horizontally under the internal half of the clavicle, and carried into the deltopectoral groove.

The subclavian artery is then dissected: its distal part can be exposed after division of the anterior scalenus muscle over the first rib for tumor-free margins. The phrenic nerve is identified and exposed on the anterior aspect of the anterior scalenus muscle; depending on its tumor involvement, it must be either carefully preserved or resected. The eventual division of branches of the subclavian artery, if invaded by tumor, is simplified after proximal control of its origin is obtained. The internal mammary artery and the ascending cervical artery are often divided, and the vertebral artery, when involved, can also be resected. When the tumor rests against the wall of the subclavian artery, the artery can be freed along a subadventitial plane. Whenever the arterial wall is involved by tumor, resection of the artery to obtain tumor-free margins is necessary; revascularization is performed either with a polytetrafluoroethylene graft (No. 6 or 8) or by end-to-end anastomosis. In middle-type tumors, the middle scalenus muscle can be extensively invaded, requiring its high division for tumor-free margins.

Extension to or compression of the brachial nerves by tumor requires an "out-in side" dissection. Secondary branches and then primary branches of the brachial plexus are freed. The lower trunk and C-8 and T-1 nerve roots can be dissected up to the spinal foramen. Although spread of the tumor to the brachial plexus can be high, neurolysis is usually achieved without need for division of branches of the brachial plexus above T-1.

Exposure of the vertebral body, sympathetic chain, and

stellate ganglion is thereafter easily obtained, and tumor that has spread to these structures can be easily resected. Once structures above the thoracic inlet have been freed from tumor and resected, the first and second ribs or any other adjacent structures, if involved, can be easily resected.

Statistical Analysis

Survival was calculated from the date of operation to death or the date of the last follow-up for patients who remained alive and disease free. Patients were followed up every 6 months by routine chest roentgenograms, computed tomographic scans of the outlet region, and any other necessary procedures already mentioned.

Results

There were ten anterior, three posterior, and one middle outlet tumors. The surgical outcome is detailed in Table 2. There were no operative deaths; 1 patient (patient 12) (7%) died on postoperative day 30 of multiorgan system failure. Two patients experienced complications: mild and short-lasting postoperative motor and sensory deficits in the C5-7 nerve roots in patient 3 and shoulder pain in patient 4.

All patients underwent radical resection of the tumor and the invaded adjacent structure or structures. This was achieved using the anterior cervical approach alone in 10 patients. In the 3 patients with a posterior tumor, the cervical approach was associated with a one-stage posterolateral thoracotomy ($n = 2$) or a median interscapular approach ($n = 1$). A median sternotomy was necessary in 1 patient (patient 12) whose tumor involved the cephalic border of the superior vena cava and in whom a right upper lobectomy was necessary.

Tumors extended to the bony, muscular, and nerve outlet structures in 8, 10, and 7 patients, respectively. Ten patients had tumor involvement of the subclavian vessels. Six of them had simple ligature ($n = 5$) or wedge resection ($n = 1$) of the subclavian vein and related branches, 1 patient had revascularization of both the subclavian vein by an end-to-end anastomosis and the subclavian artery by a ringed polytetrafluoroethylene graft (6 mm), 1 had revascularization of the subclavian artery alone (end-to-end anastomosis), and 2 patients had revascularization between the left brachiocephalic vein and superior vena cava (ringed polytetrafluoroethylene graft, 12 mm). Follow-up venograms showed complete patency of the anastomoses.

Follow-up

With a median follow-up of 3.4 years (range, 3 to 127 months), all but 1 of the operative survivors are alive and without evidence of local recurrence. None of the patients received adjuvant radiation therapy. Patients with benign lesions received no further therapy, and the 2 patients with esophageal cancer and adenocarcinoma of unknown origin were subsequently treated with systemic chemotherapy targeting the primary tumor.

There has been only one late death. Patient 5 died 21

months after operation of systemic progression of metastatic melanoma despite chemotherapy. One patient (patient 3) had local recurrence to the subscapular and trapezius muscles and residual bony scapular structure 17 months postoperatively; he underwent a successful scapulectomy and is alive and disease-free.

Illustrative Case Reports

PATIENT 2. A 59-year-old woman was seen in March 1984 with a 5-month history of a left outlet mass associated with Horner's syndrome. She denied hoarseness, weight loss, arm or shoulder pain, and muscular weakness in the left arm or hand. The results of physical examination were within normal limits. Chest radiography revealed a left apical mass mimicking an apical bronchogenic tumor (Fig 2A). Computed tomographic scan confirmed the cervical location of the mass (Fig 2B) and showed its extension into the posterior mediastinum, where osteolysis of the body of T-4 and enlargement of the corresponding intervertebral foramen (Fig 2C) were discovered. Arteriography of the left humerus demonstrated that the tumor mass was located above the superior margin of the subclavian artery, between the origin of the vertebral artery and the inferior thyroid artery and thyrobrachiocephalic trunk, which appeared dislocated and compressed (Fig 2D). Myelography confirmed an extradural medullar compression. A needle biopsy specimen was positive for schwannoma. Fiberoptic bronchoscopy and extrathoracic workup were negative. Serum laboratory values were normal.

A one-stage anterior cervical and posterior interscapular approach was performed on April 24, 1984. Through a median interscapular incision, the neurosurgeon first performed a hemilaminectomy of T-3 and T-4 with mobilization of the interspinous canal extension of a well-encapsulated tumor. The anterior cervical approach was then performed. Because of the absence of tumor invasion, dissection of all vascular and nerve outlet structures and resection of a well-encapsulated tumor lying on and compressing the superior surface of the subclavian artery and its major branches were easily performed. The patient recovered without sequelae and is alive and disease-free.

PATIENT 14. A 57-year-old woman was seen in December 1991 with a diagnosis of recurrence from radiation-induced fibrosarcoma of the right thoracic outlet, clavicle, manubrium, and first and second ribs. In January 1978, she underwent total mastectomy for a primary breast cancer; in July 1978, a primary tumor relapse occurred and was treated with bilateral ovariectomy and radiation therapy to the primary and axillary areas. She did well until 1986, when a spontaneous rupture of the internal half of the clavicle occurred, and a diagnosis of radiation-induced fibrosarcoma was made; she underwent a partial right claviculectomy. In February 1991, she experienced a recurrence to the manubrium, and a partial manubrial resection was done. In November 1991, a new recurrence was observed, and she was referred to our institution.

Physical examination revealed a painful 2 × 2-cm mass lying subcutaneously at the right margin of the manubrium and the distal part of the previously resected

Table 2. Surgical Outcome

Patient No.	Surgical Approach	Involved Bony Structure (s)	Involved Muscle(s)	Involved Nerve(s)	Involved Vessel(s)	Tumor Size (cm)	Status (mo)
1	Cervical	...	...	...	...	3 × 2	Alive (127)
2	Cervical and hemilaminectomy (T-3, T-4)	...	...	...	...	12 × 5 × 4	Alive (95)
3	Cervical and PLT	1st and 2nd ribs	SCM, ASM, 2nd intercostal muscles	PN, middle and lower BP trunks	Ligature of SV and IJV	17 × 8 × 5	Alive (51)
4	Cervical and PLT	1st rib, axillary margin of the scapula	Posterior scalene, trapezius, subscapular and serratus anterior muscles	...	...	6 × 2 × 3	Alive (49)
5	Cervical	...	Minor pectoral muscle	...	...	5 × 2 × 2	Dead (21)
6	Cervical	1st and 2nd ribs	ASM	PN	EEA of SV and artery ^a	12 × 5 × 5	Alive (46)
7	Cervical	1st rib	ASM	PN	Ligature of SV major branches	7 × 3.5	Alive (45)
8	Cervical	...	ASM	...	Ligature of IJV, IMA, and TBCS	6 × 3	Alive (41)
9	Cervical	2nd, 3rd, 4th ribs	Major and minor pectoral muscles	Lower trunk of BP	Ligature of SV; EEA of SA	9 × 1.5	Alive (17)
10	Cervical	...	...	...	Wedge of SV	8 × 2	Alive (8)
11	Cervical + scapulectomy	Rib 1	ASM, MSM, subscapular muscle	...	Ligature of major SA branches except VA	4 × 1.5	Alive (6)
12	Cervical + median sternotomy	1st and 2nd ribs	Major pectoral muscle	PN, vagus nerves	Ligature of SV, IJV, and VA; revascularization of LIV and SVC ^b	4 × 5	Dead (1)
13	Cervical	...	ASM	PN	Ligature of IMA and TBCS	3 × 2	Alive (3)
14	Cervical	1st rib, manubrium	...	PN	Ligature of IMA; revascularization of LIV and SVC ^b	6 × 3	Alive (3)

^a A ringed polytetrafluoroethylene graft (6 mm) was used. ^b The revascularization between the LIV and the SVC was done with a ringed polytetrafluoroethylene graft (12 mm).
 ASM = anterior scalenus muscle; BP = brachial plexus; EEA = end-to-end anastomosis; IJV = internal jugular vein; IMA = internal mammary artery; LIV = left innominate vein; MSM = middle scalenus muscle; PLT = posterolateral thoracotomy; PN = phrenic nerve; SA = subclavian artery; SCM = sternocleidomastoid muscle; SV = subclavian vein; SVC = superior vena cava; TBCS = thyrobricervicoscapular trunk; VA = vertebral artery.

Fig 2. (A) Chest roentgenogram showing a left apical mass mimicking an apical tumor. (B) Computed tomographic scan demonstrating a tumor mass of the thoracic outlet extending into the posterior mediastinum and inducing osteolysis of the body of T-4. (C) Computed tomographic scan showing enlargement of the corresponding intervertebral foramen. (D) Arteriogram of left humerus showing that the tumor mass was located in the area above the superior margin of the subclavian artery, between the origin of the vertebral artery and the inferior thyroid and thyrobicervicoscapular arteries; all these vessels appeared dislocated and compressed.

clavicle; she denied superior vena cava signs and symptoms, weight loss, Horner's syndrome, and right arm or shoulder pain. A preoperative computed tomographic scan (Fig 3A) confirmed the mass. The magnetic resonance imaging scan revealed major involvement of the confluence between the right brachiocephalic vein and the superior vena cava; the innominate artery was not in-

volved (Fig 3B). Superior phlebocavography showed stenosis of the caudal part of the right brachiocephalic vein, compression of the superior margin of the terminal part of the left brachiocephalic vein, and rigidity of the cephalic portion of the superior vena cava (Fig 3C).

Definitive resection was performed through an anterior transcervical approach alone. The tumor was 6 × 3 cm in

Fig 3. (A) Computed tomographic scan demonstrating a right subcutaneous tumor bulging into the underlying muscles, the right margin of the previously resected manubrium, and the distal part of the previously resected clavicle. (B) Axial magnetic resonance imaging scan showing a tumor 2 cm in diameter originating in the outlet area and extending to the confluence between the right brachiocephalic vein and the superior vena cava, without involving the innominate artery. (C) Phlebocavogram showing stenosis of the caudal part of the right brachiocephalic vein, compression of the superior margin of the terminal part of the left brachiocephalic vein, and rigidity of the superior portion of the superior vena cava.

diameter and extended proximally to the periosteum of the previously resected internal half of the clavicle, the caudal portion of the subclavian vein, the right brachiocephalic vein, the cephalic portion of the superior vena

cava, first rib, manubrium, and visceral pleura; distally, the tumor involved the phrenic nerve but not the brachial plexus. After adequate dissection and proximal and distal control of the involved veins, en bloc resection of the tumor and invaded structures was performed. Immediate revascularization between the left brachiocephalic vein and superior vena cava was accomplished by the interposition of a ringed polytetrafluoroethylene graft (12 mm). Because of the several previous surgical interventions in this area, the large skeletal defect, and the potential development of paradoxical movement, bony and soft tissue reconstruction and stabilization were achieved with Vicryl mesh (Ethicon, Somerville, NJ) and omental transposition, respectively.

Pathologic examination confirmed the initial diagnosis of radiation-induced sarcoma; all margins were free of tumor. The patient recovered without complications and was discharged on postoperative day 14.

Comment

Traditionally, radical surgical procedures for neurovascular disorders [5] and bronchogenic malignancies [6, 10] involving the thoracic outlet have been associated with high operative mortality and serious complications, such as fatal hemorrhage from the subclavian vein and artery or permanent neurologic damage to the extremity from T-1 or C-8 injury in the process of either dissecting the brachial plexus for tumor-free margins or removing the first rib. Although surgical experience with malignancies involving the thoracic outlet are limited to superior sulcus tumors [6], neoplastic involvement of the subclavian vessel and brachial plexus has long been considered a contraindication to any surgical approach because of the dismal outcome and high cost/benefit ratio.

Primary and metastatic nonbronchogenic tumors of the superior aperture of the thorax are uncommon lesions that encompass a kaleidoscopic panorama of benign and malignant bone and soft-tissue diseases, the peculiarities of which are their local aggressiveness, tendency to encapsulate the structures lying in this target area, high local recurrence rate, and, for some, propensity to metastasize [7, 8, 11]. Because of this, affected patients are highly symptomatic and may have shortened survival. The surgical management of these tumors should aim to relieve resulting thoracic outlet syndromes and minimize the risk of local recurrence through radical clearance of the tumor. Any surgical attempt is justifiable if the risks of operation are low and no other treatment option offers equivalent chance of cure.

Our results derive from a small and heterogeneous series, reflecting the rarity and variety of the disease. However, they provide evidence that primary and metastatic nonbronchogenic neoplasms of the thoracic outlet can be successfully managed by aggressive, wide, and radical surgical resection with low morbidity and mortality and encouraging long-term results. These objectives have been obtained using the described anterior transcranial approach.

Compared with other anterior [12], transaxillary [5], or

posterior [6] techniques, the transcervical approach offers several advantages: superb exposure of the entire thoracic outlet, safe dissection, and complete surgical clearance of the primary tumor mass-involved segments regardless of their anterior, middle, or posterior location. Moreover, it does not preclude complementary one-stage thoracotomy or sternotomy if resection of adjacent structures is necessary. The key to the success of this operation is the removal of the medial half of the clavicle. Resecting the clavicle and dividing its posterior periosteum and underlying subclavian muscle allows good control and deep dissection of adjacent subclavian vein, anterior scalenus muscle, phrenic nerve, and subclavian artery, and leaves no disability and minimal disfigurement. Using our transcervical approach, resection for wide, tumor-free margins of the primary lesion and involved outlet structures has never represented a major operative problem, and this is underlined by the fact that we failed to observe local tumor recurrence during follow-up. In contrast, 7 of 14 patients had an unsuccessful surgical attempt to remove the tumor before referral. This high local failure rate underscores the propensity of these tumors to recur locally and may in part be explained by the execution of a simple excision or a nonradical operation. In our opinion, to avoid the risk of tumor spread outside the affected area and to obtain a radical margin for superficial and deep-seated outlet neoplasms, the whole tumor-bearing compartment must be removed.

In the present series, the most common nonvascular outlet structures involved were the first rib (50%), anterior scalenus muscle (43%), and phrenic nerve (43%), and their resection was managed safely and effectively. Ten patients had compression or involvement of outlet vessels. Involvement of subclavian and internal jugular veins and related branches was managed by ligation after obtaining proximal and distal control because of the rich collateral circulations, without noticeable complications. Similarly, ligation of major branches of the subclavian artery, including the vertebral artery, was safely performed, provided no cerebrovascular disease was present.

In contrast, involvement of either brachiocephalic vein, the superior vena cava, and the subclavian artery often adds hazards to the operation. Two patients with a nonbronchogenic outlet neoplasm had partial invasion of the origin of the superior vena cava and the cephalic portion of the ipsilateral brachiocephalic vein. In this circumstance, clamping and prosthetic revascularization of the superior vena cava with the residual brachiocephalic vein were sufficient to maintain adequate blood flow in the graft to avoid extensive thrombosis and were not associated with intraoperative hemodynamic complications; these observations are in line with our previous experience [13]. It is equally important to avoid fatal ischemic complications of the upper limb, which have been reported [6, 10] when resection of the subclavian

artery is mandatory. In this situation, immediate revascularization either by end-to-end anastomosis, whenever technically feasible, or by vascular grafts is performed; we use externally supported polytetrafluoroethylene grafts because they tend to remain patent. Taken together, these observations should break down some of the barriers that have for so long affected the management of patients with subclavian involvement by the outlet tumor.

In summary, the proposed anterior transcervical approach may be curative not only for bronchogenic tumors extensively involving the thoracic inlet [9], but also for the infrequent and heterogeneous histologic types of non-bronchogenic tumors originating in any of the structures of this target area. To obtain wide and radical margins and thereby to keep the local recurrence rate low, the whole tumor-bearing compartment must be removed. Vascular invasion should no longer be regarded as a contraindication to surgical resection. Because of its related hazards and because many of these tumors involve vital adjacent structures, this transcervical approach should be performed by experienced surgeons representing the specialties of thoracic and vascular surgery and skin and soft tissue resection and reconstruction.

Although complement activation during cardiopulmonary bypass (CPB) is well documented, its pathogenic role in postperfusion organ injury is unproven. In this study, soluble human complement receptor type 1 (sCR1), a potent inhibitor of complement activation, was used to determine the contribution of complement activation to pulmonary injury in a porcine model of CPB. In vitro experiments demonstrated that sCR1 inhibits both classic and alternative complement pathways in the pig. Seven control piglets and 6 piglets treated with sCR1 (12 mg/kg intravenously) underwent 2 hours of hypothermic (28°C) CPB followed by 2 hours of observation. In control piglets, total hemolytic complement activity and functional activities of C3 and C5 declined to 61.3%, 67.8%, and 61.4% of prebypass values, respectively, after 2 hours of CPB. Plasma from animals treated with sCR1 had virtually no hemolytic activity (total hemolytic complement activity <5% of baseline), demonstrating effective complement inhibition. Similar degrees of neutro-

penia developed in the two groups during CPB, and there was no difference in post-CPB lung tissue myeloperoxidase level. Two hours after CPB, pulmonary vascular resistance increased 338% in control piglets but only 147% in piglets pretreated with sCR1 ($p < 0.05$); the alveolar-arterial gradient was not significantly different between controls (331 ± 52 mm Hg) and piglets receiving sCR1 (290 ± 85 mm Hg). Histologic examination revealed similar degrees of pulmonary edema in both groups. These data constitute direct evidence that complement activation plays a pathogenic role in lung injury after CPB. Although pretreatment with sCR1 ameliorated lung injury after CPB, resulting in decreased pulmonary hypertension, complement inhibition did not improve post-CPB oxygenation and had no significant effect on leukocyte kinetics or lung histology. Thus, complement participates in the pathogenesis of lung injury after CPB, but is not responsible for all of the pulmonary damage.

(*Ann Thorac Surg* 1993;55:619-24)

In the United States each year, nearly 400,000 people are placed on cardiopulmonary bypass (CPB) [1]. Although CPB supports life-saving surgical procedures, significant morbidity and mortality attend its use. A large body of evidence suggests that a portion of the morbidity associated with CPB may be attributed to the generalized inflammatory response caused by extracorporeal circulation [2, 3]. This inflammatory response involves activation of the coagulation and kallikrein cascades, the fibrinolytic system, and the complement system. Much recent work has focused on the role of complement activation in postbypass organ injury [4, 5]. Although complement activation during CPB is well documented [6, 7], its pathogenic role in postperfusion organ injury is unproven. In this study, soluble human complement receptor type 1 (sCR1, designated BRL55730 by SmithKline Beecham), a potent inhibitor of complement activation, was used to determine the contribution of complement activation to pulmonary injury in a porcine model of CPB.

Material and Methods

Surgical Manipulations

Thirteen piglets weighing 8 to 10 kg were premedicated with ketamine (40 mg/kg intramuscularly) and anesthetized with pentobarbital sodium (Nembutal; Abbott Laboratories, North Chicago, IL; 30 mg/kg intravenously). A tracheostomy was performed, and the pigs were ventilated with 100% oxygen at a tidal volume of 15 mL/kg using a volume-cycled ventilator. Positive end-expiratory pressure was set at 5 cm H₂O. A polyethylene cannula was placed in the femoral artery for pressure monitoring, and a Swan-Ganz catheter was passed through the femoral vein. Additional doses of pentobarbital sodium (50 mg intravenously) were given every 30 to 60 minutes as required. After median sternotomy, a polyethylene cannula was placed in the left atrium for pressure monitoring and blood sampling. All animals received heparin (300 U/kg intravenously). sCR1, prepared as previously described [8], was provided by T Cell Sciences, Inc, Cambridge, MA. Treated animals ($n = 6$) received sCR1 (6 mg/kg intravenously) just before the initiation of CPB and again at the conclusion of 2 hours of CPB. Control

Accepted for publication June 15, 1992.

animals ($n = 7$) received saline infusions. Cardiopulmonary bypass was initiated via cannulas placed in the right atrium and ascending aorta. A pulmonary artery vent was placed after initiation of bypass. The bypass circuit included a Sarns roller pump, a Bentley-10 Plus bubble oxygenator, and a 40- μ m in-line arterial filter. The prime consisted of 1,200 mL of a mixture of fresh homologous blood and crystalloid in a proportion calculated to produce a final hematocrit of 0.25. Animals were cooled to 28°C. Mean systemic arterial pressure was maintained at 50 to 55 mm Hg with pump flows of 80 mL/kg when temperature was greater than 32°C and 50 mL/kg when the temperature was less than 32°C. After aortic cross-clamping and cardioplegic arrest of the heart for 60 minutes, the animals were rewarmed. At the conclusion of 2 hours of CPB, an isoproterenol infusion ($0.1 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) was started and the animals were weaned from bypass. The animals were stabilized over the next 30 minutes, isoproterenol administration was discontinued, and hemodynamic measurements were recorded for 2 hours after stabilization. At the conclusion of this period, fully anesthetized animals were sacrificed by intravenous injection of potassium chloride. Portions of the right lung were removed for assessment of myeloperoxidase content. The left lung was perfusion-fixed with 300 mL of 5% glutaraldehyde in 0.15 mol/L cacodylate buffer (pH = 7.2) through the pulmonary artery and sections were removed for histologic study.

An additional 4 piglets served as surgical controls. They underwent tracheostomy, placement of monitoring lines, sternotomy, and heparinization as described above. However, they were not placed on CPB. Two of these animals received sCR1 in two divided doses as described above. Hemodynamic measurements were recorded in these 4 animals for 4 hours after surgical preparation. At the conclusion of the 4 hours, five portions of lung were removed from each untreated animal for determination of baseline myeloperoxidase (MPO) activity (see below).

Physiologic Measurements

Arterial blood gases were measured after sternotomy, every 15 minutes during CPB, and at 30, 60, 90, and 120 minutes after discontinuing CPB. Ventilation was adjusted to maintain arterial carbon dioxide tension at 30 to 35 mm Hg. Hemodynamic measurements (heart rate, mean arterial pressure, pulmonary artery pressure, left atrial pressure, and thermoluted cardiac output) were obtained after sternotomy and at 30, 60, 90, and 120 minutes after CPB. Pulmonary vascular resistance (PVR) was calculated according to the formula $\text{PVR} = 79.92 \times (\text{mean pulmonary arterial pressure} - \text{mean left atrial pressure}) / \text{cardiac output (L/min)}$. During CPB, rectal and esophageal temperature, flow rate, and mean arterial pressure were monitored continuously.

Laboratory Studies

Arterial blood samples for determination of total hemolytic complement activity (CH_{50}), functional titers of the third and fifth components of complement (C3 and C5), complete blood counts, and plasma levels of sCR1 were drawn before sternotomy; after heparinization; 15, 30, 60,

and 90 minutes after beginning CPB; and 5, 30, 60, 90, and 120 minutes after cessation of CPB. To assess pulmonary sequestration of leukocytes, simultaneous left and right atrial blood samples were drawn 5, 30, 60, 90, and 120 minutes after weaning from CPB. Complete blood counts were performed by Coulter counter, and differential cell counts were done manually. Total hemolytic complement activity was determined by the method of Mayer [9]. The titers of C3 and C5 were determined in control animals by specific functional hemolytic assay [10, 11]. All complement titers are expressed as a percentage of poststernotomy value, and all are corrected for hemodilution using the formula: corrected titer = measured titer $\times$ (poststernotomy hematocrit/hematocrit at time of measurement). Plasma sCR1 levels were quantitated by a double polyclonal bead enzyme immunoassay using specific rabbit anti-sCR1 antibodies developed by T Cell Sciences, Inc. Myeloperoxidase activity in lung tissue was assessed using a standard spectrophotometric functional assay [12]. Myeloperoxidase activity is expressed in international MPO units per gram of tissue: one unit of enzyme activity is defined as the amount of MPO that produced an absorbance change of 1.0 per minute per milligram of tissue (wet weight) at 37°C.

Histologic Examination

Perfusion-fixed samples of lung tissue were processed for hematoxylin and eosin staining and histologic examination. Samples from each lobe of the right lung were examined by a pathologist who was blinded to the treatment received by each animal.

sCR1 Activity In Vitro

Varying concentrations of sCR1 were added to various dilutions of porcine serum and then incubated with antibody-sensitized sheep erythrocytes ($1 \times 10^8/\text{mL}$) for 1 hour at 37°C to assess inhibition of the classic pathway [9] or with unsensitized rabbit erythrocytes ($1 \times 10^8/\text{mL}$) for 1 hour at 37°C to assess inhibition of the alternative pathway [13]. In either case, the percent inhibition of complement activation was determined by comparing the percent erythrocyte lysis in the serum to which sCR1 had been added with the percent lysis in the serum to which buffer had been added.

Statistical Analysis

All values are expressed as mean $\pm$ standard error of the mean. Comparisons between groups were made using analysis of variance for repeated measures. Comparisons within groups were performed with Duncan's test for multiple comparisons. Myeloperoxidase activities were compared with Student's *t* test.

Animal Care

All animals received humane care in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Fig 1. Soluble human complement receptor type 1 (sCR1) inhibition of classic and alternative pathways of complement activation in porcine serum *in vitro*. Percent inhibition of complement activation was determined by comparing percent erythrocyte lysis in serum to which sCR1 was added with percent lysis in serum to which buffer was added. Figure 1A shows inhibition of complement-mediated lysis of antibody-coated sheep erythrocytes (classic pathway) and Figure 1B demonstrates inhibition of complement-mediated lysis of rabbit erythrocytes (alternative pathway). Data are presented for three porcine serum dilutions, as indicated.

Results

Survival

All animals survived CPB and the 2-hour post-CPB observation period. One sCR1-treated animal was excluded from analysis because histologic examination of the lung revealed chronic pneumonia.

Inhibition of Complement Activation *In Vitro* by sCR1

Initial experiments were performed to determine whether human sCR1 was able to inhibit activation of the classic and alternative pathways of porcine complement. Human sCR1 inhibited the lysis of antibody-sensitized sheep erythrocytes (the classic pathway) by porcine serum at relatively low doses (Fig 1A). Similarly, human sCR1 effectively inhibited the lysis of unsensitized rabbit erythrocytes (the alternative pathway) by porcine serum (Fig 1B).

Inhibition of Complement Activation During Cardiopulmonary Bypass

Experiments were also performed to determine whether there was activation of the complement system during CPB in pigs and whether human sCR1 was capable of inhibiting that activation. There was ongoing consumption of complement during the 2 hours of CPB (Fig 2). At the final measurement, 2 hours after CPB, CH₅₀, C3, and C5 levels had declined to 61.3% ± 5.2%, 67.8% ± 8.9%, and 61.4% ± 8.4% of prebypass values, respectively. The levels of CH₅₀, C3, and C5 during and after bypass were significantly different from baseline at all measured time points ($p < 0.05$). In Figure 3, CH₅₀ values and plasma sCR1 levels are plotted for animals treated with sCR1. Plasma from these animals had virtually no hemolytic activity; the CH₅₀ value was less than 5% of baseline at all time points after sCR1 administration, indicating effective complement inhibition. The two doses of sCR1 administered during the experiment resulted in plasma sCR1 levels greater than 50 μg/mL at all time points.

Neutrophil Counts and Lung Tissue Myeloperoxidase

Neutrophil counts were similar in both groups over the entire course of the experiment (Fig 4). Significant neutropenia developed in all piglets during CPB. Neutrophil counts in control animals fell from the poststernotomy value of 5,002 ± 1,443 cells/μL to 768 ± 280 cells/μL at 90 minutes of CPB. Neutrophil counts in treated animals fell from 8,285 ± 3,134 cells/μL to 916 ± 159 cells/μL over the same period. After CPB, there was a gradual increase in neutrophil counts in both groups. Although right atrium to left atrium neutrophil gradients 5 minutes after reestablishment of pulmonary blood flow were greater in treated animals (446.2 ± 265.2 cells/μL) than in controls (175.7 ± 113.6 cells/μL) these differences were not significant ($p = 0.34$).

The mean lung tissue MPO level in animals that served

Fig 2. Total hemolytic complement activity (CH₅₀), C3, and C5 titers during cardiopulmonary bypass in control piglets. Data are expressed as percentage of poststernotomy values. All data are corrected for hemodilution. (CPB 15, 30, 60, and 90 refer to time points during cardiopulmonary bypass, and Post 30, 60, 90, and 120 refer to time points after cardiopulmonary bypass.)

Fig 3. Total hemolytic complement activity (CH_{50}) and plasma soluble human complement receptor type 1 (sCR1) levels during cardiopulmonary bypass in treated piglets. CH_{50} data are expressed as percentage of poststernotomy value and are corrected for hemodilution. sCR1 doses (6 mg/kg intravenously) were given after sternotomy and at the conclusion of 2 hours of cardiopulmonary bypass. (Sternotomy refers to after sternotomy; CPB 15, 30, 60, and 90 refer to time points during cardiopulmonary bypass, and Post 30, 60, 90, and 120 refer to time points after cardiopulmonary bypass.)

as surgical controls (sternotomy without CPB) was 0.055 ± 0.005 units/g. Postbypass lung tissue MPO levels were 0.211 ± 0.132 units/g in sCR1-treated animals and 0.217 ± 0.208 units/g in untreated animals. Although CPB caused an increase in lung tissue MPO level in both groups as compared with surgical controls, MPO levels were not significantly different between treated and untreated animals after CPB ($p = 0.98$).

Pulmonary Function

Pulmonary vascular resistance increased significantly in both groups after CPB (Fig 5). However, PVR at all points after CPB was significantly lower in treated than in untreated animals ($p < 0.05$). At 2 hours after bypass, PVR in control and sCR1-treated animals was $2,947 \pm 304$ and $1,725 \pm 311$ dynes $\cdot$ sec $\cdot$ cm $^{-5}$, respectively ($p < 0.05$).

Fig 4. Neutrophil counts during cardiopulmonary bypass in control and treated piglets. (CPB 15, 30, 60, and 90 refer to time points during cardiopulmonary bypass, and Post 30, 60, 90, and 120 refer to time points after cardiopulmonary bypass; sCR1 = soluble human complement receptor type 1.)

Fig 5. Pulmonary vascular resistance (PVR) in control and treated piglets. Poststernotomy (stern) (baseline) and postbypass (Post) values are displayed. ($p < 0.05$ for soluble human complement receptor type 1 [sCR1]-treated versus control animals by analysis of variance for repeated measures.)

There were no differences in left atrial pressure (2 to 4 mm Hg) or cardiac output (600 to 900 mL/min) between groups after CPB. Alveolar-arterial gradients for oxygen also increased significantly in all animals after 2 hours of CPB, but there was no significant difference between control and treated groups (Fig 6).

During the 4-hour observation period after sternotomy, there was no change in hemodynamic parameters or pulmonary function in any of the 4 piglets that served as surgical controls. Administration of sCR1 to 2 of these piglets had no effect on systemic or pulmonary hemodynamics or oxygenation.

Histology

Control and sCR1-treated animals had similar pulmonary histology after CPB. There were multifocal areas of pulmonary edema and neutrophil sequestration surrounded by areas of normal lung in both treated and untreated animals. Ten to 20% of each lung field had evidence of pulmonary edema.

Fig 6. Alveolar-arterial (A-a) gradients for oxygen in control and treated piglets. Poststernotomy (Stern) (baseline) and postbypass (post) values are displayed. ($p =$ not significant for soluble human complement receptor type 1 [sCR1]-treated versus control animals.)

Comment

Kirklin [2] and others [3, 4] have hypothesized that much of the pulmonary damage associated with CPB is caused by a generalized inflammatory reaction that occurs when blood is exposed to synthetic surfaces of the bypass circuit. Extracorporeal circulation causes rapid and extensive complement activation in humans [4-7]. It is generally accepted that complement is activated predominantly by the alternative pathway early in CPB and that the protamine-heparin complex causes further activation via the classic pathway [14]. Because complement activation can cause increased vascular permeability, vasoconstriction, and leukocyte chemotaxis and activation [15, 16], and each of these phenomena occurs during CPB, it has been suggested that complement activation may be responsible for the pulmonary damage seen after CPB [2-4]. Kirklin and associates [17] found that complement levels 3 hours after CPB correlate with cardiac, pulmonary, and renal dysfunction. Moore and colleagues [18] reported that extensive complement activation is associated with prolonged postoperative ventilatory support. Taken together, these studies suggest that complement activation is associated with postperfusion pulmonary dysfunction, but they do not prove that it is responsible for the injury.

Previous attempts to modulate complement activation during human CPB have included use of membrane oxygenators, steroids, and heparin-coated bypass circuits. Although membrane oxygenators have advantages over bubble oxygenators, there is no consensus that they cause less complement activation during CPB. Rather, complement activation varies with individual proprietary oxygenators, some models causing less activation than others [19, 20]. Recently, heparin-coated bypass circuits have been shown to reduce complement activation during CPB; however, they do not completely eliminate complement activation, and no physiologic benefit has been reported with use of such equipment [21]. Although steroid therapy has been associated with a moderate decrease in complement activation in some studies [22], others have found no significant effect [23].

Experimental studies have also attempted to define the role of complement activation in postperfusion organ injury. Cobra venom factor therapy causes depletion of complement; it reduced pulmonary dysfunction in sheep placed on venovenous bypass [24]. However, cobra venom factor depletes complement by causing its activation and consumption; this mechanism of action may itself cause organ damage, making results of studies employing cobra venom factor difficult to interpret. Finally, FUT-175, a nonspecific protease inhibitor, has been shown to decrease complement activation in a model CPB circuit [23], but it has not been used in an animal model of CPB. Thus, none of these attempts to decrease complement activation has provided conclusive evidence that complement activation is pathogenic in CPB.

Until now there has been no practical pharmacologic means to reduce complement activation during CPB. sCR1 is a recombinant form of human complement receptor type 1 that lacks the membrane-bound and cytoplasmic domains of the native molecule [8]. Human comple-

ment receptor type 1, which is present on normal erythrocytes, neutrophils, and other blood cells, protects these cells from bystander damage when they are present at inflammatory foci. The method of protection is believed to be inactivation of the C3 and C5 convertases [8]. sCR1 has similar biologic activity. It binds to C3b and C4b, causing degradation and inactivation of the C3 and C5 convertases of the classic and alternative pathways. It is effective *in vitro* against complement from human and rats [8]. sCR1 administration has reduced infarction size in a rat model of myocardial ischemia [8] and has been shown to delay hyperacute rejection of rat cardiac allografts in presensitized recipients [25]. Treatment with sCR1 also reduced pulmonary vascular injury in models of immune complex-induced alveolitis and cutaneous thermal injury [26]. In this study, we have used sCR1 to examine the role of complement activation in pulmonary injury produced by CPB.

Pulmonary dysfunction remains a significant problem after CPB [4, 5, 27]. The piglet is an appropriate animal for study of pulmonary injury after CPB because pigs tolerate CPB poorly, demonstrating marked stigmata of postperfusion organ injury. During CPB, increased microvascular permeability and pulmonary dysfunction develop in pigs [28]. Kirklin [2] has shown that pigs placed on CPB experience complement activation. Others have demonstrated that injection of complement-activated plasma causes hypoxemia, pulmonary hypertension, pulmonary edema, and pulmonary leukostasis in pigs [29]. In our model, CPB produced lung injury manifest as increased alveolar-arterial gradient for oxygen, increased PVR, and histologic alveolar injury. There was associated consumption of complement during CPB, with CH₅₀, C3, and C5 levels falling to approximately 60% of baseline; this is analogous to the situation in human CPB [23].

Preliminary *in vitro* studies confirmed that sCR1 effectively inhibits complement activation in pig plasma. At microgram per milliliter concentration, sCR1 inhibited both classic and alternative pathways *in vitro*. Because specific antibodies to products of porcine complement activation (C3a, C5a) are not commercially available, we were unable to perform direct measurements of complement activation during CPB. However, plasma from animals pretreated with sCR1 had virtually no hemolytic activity; this strongly supports significant inhibition of complement activation.

In this model, treatment with sCR1 significantly reduced pulmonary hypertension after CPB. The mechanism for this decrease in PVR is unclear. In preliminary experiments, sCR1 administration to animals after sternotomy without CPB resulted in no change in hemodynamics or pulmonary function. This suggests that sCR1 is not a direct pulmonary vasodilator. Treatment with sCR1 did not significantly affect post-CPB alveolar-arterial gradient, pulmonary histology, lung tissue myeloperoxidase, or leukocyte kinetics. Thus, complement inhibition reduced but did not eliminate post-CPB pulmonary dysfunction.

This result is not surprising. Cardiopulmonary bypass causes a diffuse inflammatory reaction characterized by activation of multiple humoral amplification cascades.

While CPB results in complement activation, it also causes kinin generation, consumption of coagulation factors, fibrinolysis, liberation of thromboxane A₂, and activation of platelets and neutrophils [2, 3]. Activation of the kinin system alone can result in neutrophil activation, increased vascular permeability, and vasoconstriction [2]. Neutrophils can cause tissue damage by generation of reactive oxygen species, liberation of proteases, and release of products of the arachidonic acid cascade [2, 3]. We have previously demonstrated that neutrophil depletion, like complement inhibition, reduces but does not eliminate the pulmonary injury associated with CPB [30]. This suggests that therapies targeted to only one arm of the complex inflammatory cascade initiated by CPB will not eliminate postperfusion organ injury.

In this study, we used sCR1, a potent inhibitor of complement activation, to demonstrate that complement activation participates in the pathogenesis of lung injury after CPB. However, complement activation does not account for all of the pulmonary damage in this porcine model. More effective reduction of CPB-associated organ injury will probably require modulation of other arms of the inflammatory cascade initiated by CPB or inhibition of the final common pathways of inflammation.

Cardiopulmonary Bypass and Cellular Immunity: Changes in Lymphocyte Subsets and Natural Killer Cell Activity

Kazuyoshi Tajima, MD, Fumio Yamamoto, MD, Kohei Kawazoe, MD, Izumi Nakatani, MD, PhD, Hiroshi Sakai, PhD, Toshio Abe, MD, and Yasunaru Kawashima, MD

Department of Cardiovascular Surgery, National Cardiovascular Center, Suita, Osaka; and Department of Thoracic Surgery, Nagoya University School of Medicine, Nagoya, Japan

To investigate whether cell-mediated immunity responses are suppressed or activated by the effect of cardiopulmonary bypass (CPB), we studied peripheral blood lymphocyte subsets and antibody-dependent cell-mediated cytotoxicity in 52 adult patients who had undergone open heart operations. Lymphocyte function also was studied with regard to mixed lymphocyte reaction, which indicates the amount of DNA synthesis of lymphocytes, and natural killer (NK) cytotoxicity, which represents the killing activity of NK cells on the tumor cells (K-562), in 11 patients. The total T lymphocyte (OKT3+ and OKT11+) number showed no significant change during CPB. Suppressor/cytotoxic T cell (OKT8+)

and NK cell (Leu7+ and Leu11+) numbers were found to be remarkably increased. However, helper/inducer T cell (OKT4+) and B cell (Leu12+) numbers were decreased during CPB. Antibody-dependent cell-mediated cytotoxicity was elevated during CPB. All of these changes were almost returned to the preoperative levels by the seventh day after operation. Mixed lymphocyte reaction and NK cytotoxicity were also activated during CPB. The results show that heart operations in which cardiopulmonary bypass is used are associated with activation of cytotoxic cell-mediated immunity.

(*Ann Thorac Surg* 1993;55:625-30)

Because cardiopulmonary bypass (CPB) used in open heart operations is a nonphysiological assisting device, it has been considered to cause specific changes in immunity and lead to development of postoperative infections. The possibilities of graft-versus-host diseases developing after open heart operation are relatively high. Taking account of these findings, the specificity of immunological changes in cardiac operations, including changes in mitogenic responsiveness, is now the subject of investigation. Furthermore, understanding the alterations in lymphocyte functions in open heart operations is important as a control study for immunological monitoring of rejection in heart transplantation. In this report, we examined the effect of cardiac operation on cell-mediated immunity by comparing the changes in each lymphocyte subset. Because natural killer (NK) cells showed a very interesting change, we performed further investigations of mixed lymphocyte reaction (MLR) and NK cytotoxicity to define the significance of the changes in this nonspecific immunity during CPB.

Material and Methods

Lymphocyte Subsets and Antibody-Dependent Cell-Mediated Cytotoxicity

We studied 52 adult patients, 35 men and 17 women, who underwent open heart operation at the National Cardiovascular Center. Mean age of the patients was 54.6 ± 12.9 (standard deviation). Twenty-three patients had valvular disease, 25 had ischemic heart disease, and 4 had other diseases. Mean CPB time was 160.2 ± 50.0 minutes, and the following oxygenators were used: bubble: Bard H-1700, 10 patients; polyethylene membrane: Bard HF4000, 10 patients; polypropylene membrane: Travenol LPM50, 10 patients; Cobe IF-CML, 11 patients; and silicone membrane: MERA HSO-2.5, 11 patients.

ANALYSIS OF LYMPHOCYTE SUBSETS. Changes in peripheral blood lymphocyte subsets were measured by flow cytometric analysis using monoclonal antibodies as follows: OKT3(CD3), OKT4(CD4), OKT8(CD8), and OKT11(CD2) from Ortho Diagnostics Inc; and Leu7(K cell and NK cell subsets), Leu11(CD16), and Leu12(CD19) from Becton Dickinson Inc.

Blood samples were taken preoperatively (before anesthetizing), when the CPB was turned on, when it was turned off, and on the first, second, fifth, and seventh postoperative days. Measurements were calculated by multiplying the number of lymphocytes times the ratio of each subset, and then correcting for the influence of blood

dilution with the hematocrit value. No steroids were used while the CPB was on and after operation, but 100 mg/L of betamethasone was contained in the cardioplegic solution.

ANTIBODY-DEPENDENT CELL-MEDIATED CYTOTOXICITY. Peripheral blood lymphocytes (200 counts/0.1 mL) and MOLT cells (target cells: 200 counts/0.1 mL) were mixed in Falcon plastic tube and incubated in 5% carbon dioxide for 6 hours at 37°C. After that all cells secreting immunoglobulin were measured by plaque assay using protein A (Pharmacia Fine Chemicals, Uppsala, Sweden) coupled sheep red cells. Antibody-dependent cell-mediated cytotoxicity is presented as a percentage: (plaque forming cells/total lymphocytes) $\times$ 100%.

Lymphocyte Function

To understand the changes in lymphocyte function during CPB, we examined MLR and NK activity. Lymphocytes were obtained from 11 adult patients (7 men and 4 women) who underwent open heart operation. The average age was 52.9 ± 10.0 years. Two patients had ischemic heart disease, and 9 patients had valvular disease. Oxygenators used were Maxima (7 patients), BOS-10 (3 patients), and HF4000 (1 patient).

MIXED LYMPHOCYTE REACTION. Lymphocytes were separated from peripheral blood samples, and only viable ones were counted. These lymphocytes were suspended in RPMI 1640 medium containing 10% fetal calf serum and adjusted to a concentration of $1 \times 10^5/0.1$ mL per well. The number of wells was 96 per microplate (Corning Co). Peripheral blood lymphocytes of 10 normal adult donors were treated with 20 Gy radiation. An equal volume of this lymphocyte suspension was added to each well as a stimulator. The lymphocytes were incubated in 5% carbon dioxide for 7 days at 37°C. These lymphocytes were then labeled with 1 μ Ci of tritium thymidine per well, incubated for an additional 16 hours, and harvested. As an index of the amount of DNA synthesis, the uptake of tritium thymidine was measured in a liquid scintillation counter. The result is presented as stimulation index: = allogenic lymphocyte activity (counts/min)/autologous lymphocyte activity (counts/min).

NATURAL KILLER CELL ACTIVITY. Lymphocytes separated from peripheral blood samples (effector cells) and K-562 cells labeled with chromium 51 (target cells) were mixed in RPMI 1640 medium containing 10% fetal calf serum with effector/target ratios of 60:1, 30:1, and 15:1, and incubated in 5% carbon dioxide for 6 hours at 37°C. After incubation, NK cytotoxicity was calculated from the radioactivity of chromium 51 in the supernatant and is presented as percent lysis = (experimental release - spontaneous release)/(maximum release - spontaneous release) $\times$ 100%. (Maximum release is total radioactivity in target cells.)

Results are presented as the mean $\pm$ the standard deviation, and the significance of the differences between the mean values was analyzed by paired two-tailed Stu-

Fig 1. Absolute levels of circulating OKT3+ cells and OKT11+ cells after cardiac operation (mean $\pm$ standard deviation of the mean). No significant differences were found between before and after cardiopulmonary bypass. (ANE = induction of anesthesia; CPB = cardiopulmonary bypass; NS = not significant; POD = postoperative day.)

dent's *t* test for lymphocyte subsets and antibody-dependent cell-mediated cytotoxicity and Wilcoxon signed-ranks test for MLR and NK activity using the StatView program on a Macintosh Computer SE (Apple Computer Inc). A *p* value of less than 0.05 was considered significant.

All the patients were given detailed information on the design and aim of the study and then gave their consent to participate.

Results

Lymphocyte Subsets

OKT3+ AND OKT11+ CELLS. The number of OKT3+ cells, which indicates the total number of lymphocytes, and the number of OKT11+ cells, which indicates the number of E rosette formation T lymphocytes, were $1,431 \pm 589$ and $1,615 \pm 614/\mu$ L before CPB, respectively, but decreased prominently to 417 ± 301 and $555 \pm 369/\mu$ L, respectively, on the first postoperative day. These numbers, however, rose gradually after the first day and recovered to the preoperative levels on the seventh day after operation. The changes in the numbers of OKT3+ and OKT11+ cells during CPB were not significant (Fig 1).

OKT4+ AND OKT8+ CELLS. The number of OKT4+ cells, which indicates helper/inducer T cells, started decreasing during CPB ($p < 0.01$) and reached the lowest level on the first day after operation. In contrast, the number of OKT8+ cells, which indicates suppressor/cytotoxic T cells, increased during CPB ($p < 0.01$), but on the first postoperative day dropped to the lowest level. Both of them recovered to the preoperative levels or higher after a week (Fig 2).

Leu7+ AND Leu11+ CELLS. The numbers of Leu7+ and Leu11+ cells, which indicate NK cells, were 336 ± 260 and

Fig 2. Absolute levels of circulating OKT4+ cells and OKT8+ cells after cardiac operation. The number of OKT4+ cells was decreased during cardiopulmonary bypass. (Abbreviations are as in Figure 1.)

398 ± 251/μL, respectively, before operation, and both of them increased remarkably during CPB to 389 ± 272 and 738 ± 446/μL, respectively ($p < 0.01$). The ratio of Leu7+ and Leu11+ cells to total lymphocytes also rose prominently from 13.2% ± 9.8% to 19.2% ± 12.8% in the case of Leu7+ and from 20.3% ± 11.3% to 33.1% ± 15.8% in the case of Leu11+. This result shows the real possibility of activation in nonspecific immunity during CPB. The numbers of Leu7+ and Leu11+ cells, however, decreased on the first postoperative day and kept decreasing until the seventh day (Fig 3).

Leu12+ CELLS. The level of Leu12+ cells, which corresponds to that of B cells, reduced during CPB significantly ($p < 0.0001$), and it took a week for the Leu12+ cell level to recover (Fig 4). However, every patient showed differ-

Fig 4. Absolute levels of circulating Leu12+ cells after cardiac operation. The number of Leu12+ cells was significantly reduced during cardiopulmonary bypass. (Abbreviations are as in Figure 1.)

ent degrees of change after operation, making it impossible to delineate a tendency in the change of Leu12+ cells in the postoperative period.

CARDIOPULMONARY BYPASS TIME AND NATURAL KILLER CELLS. The degree of change in lymphocyte subsets during CPB varies with the kinds of oxygenators used [1]. In particular, the change in NK cells was remarkable when the HF4000 oxygenator (Bard) and the MERA silicone membrane oxygenator were used. Thus we chose 20 patients in whom these two oxygenators were used and searched for the correlation between CPB time and an increase in Leu11+ cells during CPB. There was linear regression ($r = 0.936$; $p < 0.01$) on 7 selected data points, which was obtained using the StatView program of Macintosh computer SE (Apple Computer Inc) between them up to 150 minutes of CPB time in a scatterplot that clearly shows no linear correlation at all if all data points were included (Fig 5).

ANTIBODY-DEPENDENT CELL-MEDIATED CYTOTOXICITY. Antibody-dependent cell-mediated cytotoxicity activity, which represents the magnitude of K cell cytotoxicity, increased during CPB from 4.37% ± 1.94% to 5.61% ± 2.45% ($p < 0.0003$), but diminished on the first postoperative day and returned to the preoperative level by the seventh day after operation (Fig 6).

Mixed Lymphocyte Reaction and Natural Killer Cell Activity

The stimulation index calculated from MLR was 2.02 ± 0.92 before CPB and increased to 3.26 ± 1.99 after CPB ($p < 0.05$). Natural killer activity also rose significantly from 22.95% ± 12.2% to 27.99% ± 12.27% in the 30:1 culture ($p < 0.02$) (Fig 7). These results indicate a proliferation of blastogenesis and the activation of NK cells during CPB. However, the MLR started decreasing on the first post-

Fig 3. Absolute levels of circulating Leu11+ cells and Leu7+ cells after cardiac operation. Both of them were significantly increased during cardiopulmonary bypass. (Abbreviations are as in Figure 1.)

Fig 5. Relationship between cardiopulmonary bypass (CPB) time and the increase in Leu11+ cells during cardiopulmonary bypass. There was a significant correlation ($y = -50.5 + 0.65x$; $r = 0.936$; $p < 0.01$) between them up to 150 minutes (solid circles). However, if the data points at greater than 150 minutes (open circles) are included, this correlation becomes inconsistent.

operative day, whereas NK activity kept increasing until the seventh day after operation.

Comment

It has been reported that the body's ability to protect itself against infection is reduced during CPB in open heart operations due to a reduction in immunoglobulin and complement caused by blood dilution, physical cell destruction, and protein degeneration [2]. In this regard membrane oxygenators are considered more advanta-

Fig 6. Changes in antibody-dependent cell-mediated cytotoxicity (ADCC) activity after cardiopulmonary operation. The ADCC activity was significantly increased during cardiopulmonary bypass. (Abbreviations are as in Figure 1.)

Fig 7. Changes in stimulation index (SI) of mixed lymphocyte reaction (MLR) and natural killer (NK) activity in 30:1 culture during cardiopulmonary bypass (CPB). Both of them were increased significantly.

geous than bubble oxygenators [3]. One of the major reasons for the complement reduction is its own consumption, caused by the increase in activity induced by the interaction between blood and foreign materials such as those used in oxygenators [4, 5]. The physical and chemical influence of CPB cannot be ignored, but the movement of complement mentioned above suggests to us the importance of the immunological reaction as an effect of CPB on the immune system. This immunological reaction can be seen in cell-mediated immunity as well as in humoral immunity. Because the degree of complement activation during CPB varies with which oxygenators are used [6], the immunological reaction is also presumed to occur in the oxygenators in the case of cell-mediated immunity. The immunological reaction caused by blood-artificial membrane interactions has already been studied in the field of dialysis, and the finding of promotion of interleukin-1 production indicates the activation of parts of cell-mediated immunity [7, 8]. Similar reaction to that in dialysis can be expected in membrane oxygenators.

The change in lymphocytes should be examined by their numbers and also their functions. Many studies have demonstrated that immunity is impaired in extracorporeal circulation using CPB as far as the number of lymphocytes is concerned. Roth and associates [9] reported a reduction in the total number of T cells. According to Ide and associates [10], the total number of T lymphocytes and B lymphocytes was markedly reduced during CPB, and this reduction in total T lymphocytes resulted from the reduction of helper/inducer T cells. Furthermore, Hisatomi and associates [11] reported that the number of OKT3+, OKT4+, and OKT8+ cells decreased significantly on the first or third postoperative day. In their studies, however, the number of total T lymphocytes was obtained without considering blood dilution during CPB, and each subset was compared by the composition of population to total lymphocytes, not by the absolute number. On the other hand, a reduction in the ratio of helper T cells to cytotoxic/suppressor T cells

was observed during CPB by Navarro and associates [12], and an increase in cytotoxic/suppressor T cells was suggested to contribute to the reduction in the ratio of helper T cells to cytotoxic/suppressor T cells. These findings are in agreement with our present report.

In examining immunity in open heart operations using CPB, the issue of blood dilution is always a matter of consideration. When investigating the change in immunity of an individual patient, the effect of blood dilution is one of the variables and does not need to be corrected for, but, as in our present study, it should be corrected for when the effect of oxygenators is examined. Total number of T and B lymphocytes decreased during CPB and remained decreased for a week after operation, as shown in other reports [9, 11]. Among lymphocyte subsets that we examined, the change in helper/inducer T cells was similar to that in total T lymphocytes and showed the lowest level on the first postoperative day. Because blood is diluted immediately after operation, the level of T cells, especially the helper/inducer T cell level of each patient, was quite low. Destruction and consumption of lymphocytes themselves during CPB and loss of ability to react against monoclonal antibodies due to the physical destruction of surface markers are also presumed to be responsible for this T cell level reduction. Under such conditions, however, the level of suppressor/cytotoxic T cells showed a clear increase during CPB. The number of NK cells also increased during CPB. This increase was so obvious that we noticed it before correcting for the effect of blood dilution.

We did not perform further individual examinations of suppressor T cells and cytotoxic T cells. However, if the change in suppressor T cells and cytotoxic T cells is responsible for the increase in OKT8+ cells during CPB, it is possible to say that the absolute number of lymphocytes with cytotoxicity increases during CPB. Although the mechanism of such a quantitative change has not been defined yet, Ide and associates [10] suggested T cell redistribution between bone marrow and peripheral blood as a mechanism of quantitative change in helper/inducer T cells during CPB. In the case of NK cells, suppressor T cells, and cytotoxic T cells, T cell distribution between peripheral blood and lymphoid tissue is also presumed to be a mechanism of their quantitative change. We took into consideration the effect of blood transfusion during CPB on changes in immunity. In our study, the number of both Leu11+ and OKT8+ cells increased during CPB in a nontransfusion group. There was no significant difference between changes in the transfusion group and the nontransfusion group.

In parallel with the examination of quantitative changes, MLR and NK activity were measured to determine their influence on each lymphocyte function. Both MLR and NK activity showed an increase during CPB. Natural killer activity particularly showed an increase on the first operative day. Furthermore, antibody-dependent cell-mediated cytotoxicity activity, which indicates cytotoxicity of monocytes or K cells, increased clearly during CPB. These tests, however, were performed using only

viable lymphocytes selected from samples. Therefore these findings do not immediately lead to the augmentation of lymphocyte function in each patient. Depressed lymphocyte blastogenesis has been reported during the early postoperative period [9, 13, 14]. Ryh nen and associates [15] reported that NK cell activity decreased on the second day after an open heart operation. Those studies, however, show the changes after the first postoperative day. In our study we observed the MLR increase as mentioned above, but it occurred immediately after operation, and on the first postoperative day it decreased as in the previous reports. On the other hand, Haeffner-Cavaillon and associates [16] suggested that CPB causes an increase in interleukin-1 activity in monocytes. Their report indirectly supports our findings, which demonstrate the activation of relatively primary cytotoxic immunity. Omokawa and associates [17] noted that blood-material interactions in dialysis enhance the interleukin-1 activity after 30 minutes up until 3 hours after extracorporeal circulation is started and that the enhancement is prominent when polyethylene is used as a dialyzer. Because polyethylene or polypropylene is commonly used for membrane oxygenators, a similar reaction may be expected. According to Ryh nen and associates [18], the number of antibody secreting cells (mostly B cells) and OKIa+ cells (activated T cells) in peripheral blood showed a tendency to increase after a cardiac operation, which indicates the possibility for part of the cell-mediated immunity to be activated during CPB.

We cannot determine if the cell-mediated immunity in each patient is activated or suppressed overall during CPB. The number of T cells decreases, but the viability of each cell is different. In this study CPB showed the possibility of activating cytotoxic cell-mediated immunity. Natural killer cells especially increased in number and function during CPB. This fact enables us to presume there is an increase in cytotoxicity in each patient.

Like a dialyzer during dialysis [17], the oxygenator, which is the largest contact area for blood and artificial material, is presumed to be the most likely place for immunity activation. However, if the operation is protracted, blood-material interactions may occur in the other contact areas such as cardiopulmonary bypass tubes and pumps. There is a report that shows an increase in activated suppressor/cytotoxic T cells after artificial heart implantation [19]. T nnesen and associates [20] suggested in their case report that transient augmentation of NK cell activity during CPB is related to the increasing level of blood adrenaline; however, NK cell activity decreased after operation because of an increased plasma cortisol level due to prolonged adrenaline infusion.

In our study there was a positive correlation coefficient between the number of NK cells and CPB time within a certain duration (within 150 minutes), but after 150 minutes of CPB the number of NK cells did not always increase. Although we failed to prove a direct linkage, the result implied that extended CPB might cause suppressed immunity, which could be due to saturation or damage of the epitopes or secondary hormonal effect.

Relation Between Choice of Prostheses and Late Outcome in Double-Valve Replacement

Paul S. Brown, Jr, MD, Charles S. Roberts, MD, Charles L. McIntosh, MD, PhD, Julie A. Swain, MD, and Richard E. Clark, MD

Surgery Branch, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland

The purpose of this study was to determine if the combination of a mechanical and bioprosthetic valve in the aortic and mitral positions influences late morbidity and mortality when compared with patients who had dual mechanical or dual bioprosthetic valves inserted. We reviewed the course of 89 hospital survivors of combined aortic and mitral valve replacement. The mean postoperative follow-up interval was 6.6 years, with a total follow-up of 583 years (98% complete). At 12 months after operation, mean functional class decreased from 3.1 to 1.7 ($p < 0.05$) and mean cardiac index increased from 2.1 to 2.5 $\text{L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ ($p < 0.05$). Actuarial survival for the 89 patients (exclusive of <30-day or in-hospital mortality, 14%) was 70%, 51%, and 33% at 5, 10, and 15 years. Freedom from reoperation was 93%, 78%, and 68%, and freedom from combined thromboembolism and anticoagulant-related hemorrhage was 82%, 60%, and 50%. These results show that there was no difference in overall survival in patients with dual mechanical valves, dual bioprosthetic valves, or a combina-

tion of both types at 15 years. There was, however, a lower reoperation rate in the group with dual mechanical valves as compared with the group with dual bioprosthetic valves ($p < 0.05$ at 10 years) or with a combination of valves ($p < 0.05$ at 15 years). The higher the number of mechanical valves the higher the combined risk of thromboembolism and anticoagulant-related hemorrhage. Patients who received one or two Starr-Edwards prostheses had significantly higher rates of thromboembolism and anticoagulant-related hemorrhage and a lower survival than those who received other valve combinations. Patients who received two Hancock bioprostheses had significantly higher rates of reoperation and a decreased incidence of combined thromboembolic and anticoagulant-related hemorrhagic events ($p < 0.05$ at 10 years). We conclude that combining a mechanical prosthesis and a bioprosthesis in the same patient is disadvantageous.

(*Ann Thorac Surg* 1993;55:631-40)

Late results of combined aortic and mitral valve replacement at the same operation using various types of mechanical and bioprostheses have been reported [1-10]. Few reports, however, have compared late results of simultaneous left-sided cardiac valve replacement (as the patient's first cardiac operation) at the same institution using different types of substitute valves [11-26]. The purpose of this study was to determine if the combination of a mechanical aortic and a bioprosthetic mitral valve influences late morbidity and mortality when compared with patients who had dual mechanical or bioprosthetic valves inserted.

Material and Methods

A total of 172 patients underwent simultaneous aortic and mitral valve replacement at the National Heart, Lung and Blood Institute from 1970 to 1989. Eighty-three were excluded from this analysis of late results for the following

reasons: previous cardiac operations, 41; death within 30 days of operation or during initial hospitalization, 24; severe concomitant coronary artery disease, 17; or hypertrophic cardiomyopathy, 1.

The remaining 89 patients form the basis of this report and were separated into five groups based on the types of substitute valves implanted. Thirty-four patients received dual Starr-Edwards ball and cage prostheses (SE-SE, 1970-1984), 14 received a Starr-Edwards aortic prosthesis and a Hancock mitral bioprosthesis (SE-H, 1972-1977), 19 received dual Hancock bioprostheses (H-H, 1975-1984), 12 received a Björk-Shiley tilting-disk aortic prosthesis and a Hancock mitral bioprosthesis (BS-H, 1974-1978), and 10 received dual St. Jude Medical prostheses (SJM-SJM, 1984-1987) (Table 1).

The ages at operation ranged from 15 to 69 years (mean, 50 years); 66% were male. The patients in the SJM-SJM group were younger (41 versus 52 years) than those in the other groups ($p < 0.05$). Six of the 89 patients were less than 30 years of age, and 2 were less than 20 years of age. Sixty-six patients had cardiac catheterization both before (<6 months) and after valve replacement (<9 months).

The 83 patients who were excluded had the following valves implanted (early mortality in parentheses): SJM-SJM, 4 (1); SE-SE, 19 (5); SE-H, 21 (6); BS-H, 12 (5); and

H-H, 27 (7). There were no significant differences between the patients who were excluded because of early death and the remaining 89 patients in terms of the type of valves or combinations of valves that were inserted. Although different valve combinations were placed over different time periods, it is expected that the numerous advances in myocardial protection and surgical technique would have a greater influence on short-term as opposed to long-term survival.

The end of the study was January 1, 1989, and all patients who were still alive were contacted within 2 months of this date. Follow-up was achieved primarily by yearly outpatient clinic visits, the records of which were reviewed. The duration of follow-up per patient ranged from 0.2 to 19 years (mean, 6.6 years), with a total of 583 years for 89 patients (98% complete). Follow-up was incomplete in 3 patients in that it was not known if they were alive or dead at the completion of the study. They were removed from analysis at their last clinic visit and were treated as lost to follow-up, not as having died.

The population of patients of the Surgery Branch of the National Heart, Lung and Blood Institute was unusual in that there was accurate follow-up of all patients in the outpatient clinic every 1 to 2 years for life. All underwent complete preoperative evaluation, and 74% of the 89 patients had a postoperative cardiac catheterization at less than 9 months during a rehospitalization for extensive studies. A physical examination, electrocardiogram, chest radiogram, and echocardiogram were obtained at each clinic visit. Any patient with a change in symptom complex or new echocardiographic findings underwent cardiac catheterization. If a clinic appointment was missed, the patient and the private physician were contacted to find out the status of the patient. Outside cardiac catheterization results were entered into the database as was the cause of death or autopsy results.

Morbidity and mortality results for each group were expressed in both linearized (percent/patient-year) and actuarial terms. Preoperative and postoperative data between groups were compared using unpaired Student's *t* tests, and data within the same group were compared using paired Student's *t* tests. Kaplan-Meier actuarial data were compared by the Mantel-Haenszel test.

Total mortality included all deaths during the follow-up period (Table 2); however, in the actuarial survival analysis, the 3 patients who were lost to follow-up and those who underwent reoperation or who died of trauma or cancer were withdrawn from further analysis on that particular date and were not treated as having died. The actuarial analysis of complications (thromboembolism, anticoagulant-related hemorrhage, and reoperation) included only first events, fatal or nonfatal.

Thromboembolism was defined as any new postoperative neurological or systemic ischemic deficit, whether central or peripheral, temporary or permanent. Patients receiving anticoagulant or antiplatelet agents who had episodes of hemorrhage causing death, stroke, hospitalization, transfusion, or operation were classified as having anticoagulant-related hemorrhage [27]. Those patients taking warfarin but with subtherapeutic prothrombin

Fig 1. Actuarial curves of freedom from reoperation, death, and all valve-related late morbidity and mortality (M+M) in 89 hospital survivors of combined aortic and mitral valve replacement.

times at the time of a morbid event were classified as having a thromboembolic event rather than an anticoagulant-related hemorrhage. In the patients receiving warfarin, a prothrombin time of 1.5 to 2 times normal was recommended.

Valve-related morbidity and mortality includes all late deaths, reoperations, thromboembolism, and anticoagulant-related hemorrhage. The 6 patients who died in congestive heart failure with normal valves and those who died of cancer or trauma were specifically excluded at the time of their deaths. Note that this is a measure of valve-related late morbidity and mortality and specifically excludes less than 30-day and in-hospital mortality, which was 13% (8% for reoperations and 5% for the initial operation). In the group of patients who were excluded because of early mortality, only 1 of 24 patients (with an H-H valve combination) had a thromboembolic event at less than 30 days and eventually died of pneumonia.

Results

No differences in frequency of rheumatic fever, infective endocarditis, or atrial fibrillation, duration of symptoms of cardiac dysfunction, functional class, mean preoperative pulmonary arterial pressure, cardiac index, or distribution of types of hemodynamic valvular lesions were noted among the five groups of patients (see Table 1). When the data were combined into three groups consisting of patients with dual mechanical valves, a mechanical aortic valve plus a bioprosthetic mitral valve, and dual bioprosthetic valves, there were no differences in the above parameters (see Table 1).

Survival

The actuarial survival for the 89 patients (exclusive of in-hospital or <30-day morbidity) was 92%, 70%, 51%, and 33% at 1, 5, 10, and 15 years (Fig 1). The mean postoperative functional class of all five groups decreased from 3.3 to 1.7 ($p < 0.05$), pulmonary arterial pressure decreased from 56/26 to 39/19 mm Hg ($p < 0.05$), and

cardiac index increased from 1.7 to $2.1 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ ($p < 0.05$). When the data were grouped according to patients with dual mechanical valves versus dual bioprosthetic valves or a combination of a mechanical and a bioprosthetic valve, there were significant decreases in pulmonary pressures and improvements in functional class in all groups, without differences between the groups ($p < 0.05$). The cardiac index significantly increased in the groups with either dual mechanical or dual bioprosthetic valves ($p < 0.05$) but did not significantly increase postoperatively in the group with combined mechanical and bioprosthetic valves (see Table 2).

The actuarial survival of the SE-H group at 5 and 10 years was 56% and 14% and was lower than that of the other groups ($p < 0.05$). At 10 years, the survival of the patients with one or two Starr-Edwards prostheses was lower than that of the other three groups followed up for at least 10 years ($p < 0.05$). At 3 years, the actuarial survival in the SJM-SJM group was 100%, which was higher than that of the other four groups ($p < 0.05$) (Fig 2). When the patients were reorganized into groups with dual mechanical valves, dual bioprosthetic valves, or one of each, there were no differences in actuarial survival between any of the groups at 10 years (51%) (Fig 3) or in percent deaths per 100 patient-years (8% to 10%) (see Table 2).

Fifty-four patients had died by the end of the follow-up period, 29 of whom underwent autopsy. Eleven of these patients died of consequences of strokes, believed to result from emboli in 9 and from intracerebral hemorrhage in 2 (while taking warfarin). The others died of chronic congestive heart failure without evidence of valvular dysfunction (1), acute myocardial infarction (4), lung cancer (5), trauma (2), and after reoperation to replace or repair one or both left-sided prosthetic valves (6). Three of the later patients died in the hospital and the other 3 died at some later date. The other 25 patients who were without autopsies were not specifically thought to have

Fig 2. Comparison of actuarial curves of freedom from death in 89 hospital survivors of combined aortic and mitral valve replacement with five different combinations of substitute valves. (BS = Björk-Shiley [tilting-disc]; H = Hancock; SE = Starr-Edwards; SJM = St. Jude Medical.)

Fig 3. Comparison of actuarial curves of freedom from death in 89 hospital survivors of combined aortic and mitral valve replacement with three different combinations of substitute valves: mechanical, bioprosthetic, and a combination of the two.

died of any of the above problems and were treated as valve-related mortality.

Reoperation

Actuarial freedom from reoperation for all 89 patients was 100%, 93%, 78%, and 68% at 1, 5, 10, and 15 years (see Fig 1). Forty-five bioprostheses were inserted, of which 5 (11%) were removed for structural deterioration. There were no differences in reoperation at 5 years among groups (Fig 4); however, at greater than 10 years, the SE-SE group had a higher freedom from reoperation than those groups with one or two bioprosthetic valves ($p < 0.05$) (see Fig 4). There was a higher freedom from reoperation at greater than 10 years in the group with two mechanical valves compared with the groups with the combination of a mechanical and a bioprosthetic valve or dual bioprosthetic valves ($p < 0.05$) (Fig 5). The patients with SJM-SJM prostheses were free from reoperation at 3 years.

Fig 4. Comparison of actuarial curves of freedom from reoperation in 89 hospital survivors of combined aortic and mitral valve replacement with five different combinations of substitute valves. (BS = Björk-Shiley [tilting-disc]; H = Hancock; SE = Starr-Edwards; SJM = St. Jude Medical.)

Fig 5. Comparison of actuarial curves of freedom from reoperation in 89 hospital survivors of combined aortic and mitral valve replacement with three different combinations of substitute valves: mechanical, bioprosthetic, and a combination of the two.

Reoperation was performed in 10 (11%) of the 89 patients, a frequency of 1.7 per 100 patient-years (Table 3). In the SE-SE group, 2 of 34 patients underwent reoperation: 1 had severe hemolytic anemia due to prosthetic cloth wear and 1 had a perivalvular leak. In the SE-H group, 2 of 14 patients underwent reoperation: 1 had structural deterioration of the Hancock mitral bioprosthesis and 1 had aortic and mitral perivalvular leaks. In the BS-H group, 4 of 12 patients had reoperation: 3 patients had structural deterioration of the Hancock bioprostheses in the mitral position and 1 patient had a mitral perivalvular leak and aortic prosthetic valve thrombus. In the H-H group, 2 of 19 patients underwent reoperation, 1 patient for structural deterioration of the Hancock mitral bioprosthesis and 1 patient for infective endocarditis involving both bioprostheses.

Thromboembolism

Actuarial freedom from combined thromboembolism and anticoagulant-related hemorrhage for the 89 patients was 87%, 82%, 60%, and 50% at 1, 5, 10, and 15 years (Fig 6). At 5 and 10 years, freedom from these events was 92% and 71% in the BS-H group, 89% and 75% in the H-H group, 67% and 45% in the SE-H group, and 72% and 55% in the SE-SE group. Freedom from these events at 15 years was 40% in the SE-SE group and 71% in the BS-H group. The differences among the groups did not achieve statistical significance at 5 years (Fig 7). The patients with one or two Starr-Edwards prostheses, however, had a significantly higher frequency of combined thromboembolism and anticoagulant-related hemorrhage when compared with the other groups at 10 years ($p < 0.05$) (see Fig 7). When the groups were compared according to mechanical valves, bioprosthetic valves, or a combination of the two types, there were no differences at 5 years; however, the three groups were significantly different from each other at 10 years. The group with dual mechanical valves had a higher incidence of thromboembolic and anticoagulant-related events than did the group with one mechanical

^a Or before hospital discharge. ^b Valvular repair. ^c Prophylactic aortic valve replacement.

AVR = aortic valve replacement; BS = Björk-Shiley (tilting-disc); CD = calcific deposits; IE = infective endocarditis; M = male; MVR = mitral valve replacement; SE = Starr-Edwards; TVR = tricuspid valve replacement.

Fig 6. Actuarial curves of freedom from thromboembolism (TE), anti-coagulant-related hemorrhage (ARH), and combined TE and ARH in 89 hospital survivors of combined aortic and mitral valve replacement.

valve, which had a higher incidence of thromboembolic events than the group with dual bioprostheses ($p < 0.05$) (Fig 8).

Thromboembolism occurred in 21 patients (3.6 per 100 patient-years). Nine events were fatal (1.5 per 100 patient-years). The frequency of thromboembolism per 100 patient-years was 7.2 in the SE-H group, 3.8 in the SE-SE group, 3.2 in the H-H group, and 1.8 in the BS-H group. No thromboembolic events occurred in the SJM-SJM group during 20 patient-years of observation. The actuarial curve of thromboembolism was significantly lower than that of anticoagulant-related hemorrhage at 10 years (60% versus 90%; $p < 0.05$) (see Fig 6). The actuarial curves of first thromboembolism alone paralleled the incidence of combined thromboembolism and anticoagulant-related hemorrhage (Fig 9; see Fig 7). Patients with one or two Starr-Edwards valves had a lower freedom

Fig 7. Comparison of actuarial curves of freedom from combined thromboembolism (TE) and anticoagulant-related hemorrhage (ARH) in 89 hospital survivors of combined aortic and mitral valve replacement with five different combinations of substitute valves. (BS = Björk-Shiley [tilting-disc]; H = Hancock; SE = Starr-Edwards; SJM = St. Jude Medical.)

Fig 8. Comparison of actuarial curves of freedom from combined thromboembolism (TE) and anticoagulant-related hemorrhage (ARH) in 89 hospital survivors of combined aortic and mitral valve replacement with three different combinations of substitute valves: mechanical, bioprosthetic, and a combination of the two.

from thromboembolism than the other groups at 10 years ($p < 0.05$). When the groups were compared according to mechanical valves, bioprosthetic valves, or a combination of the two types, there were no differences in thromboembolism at 10 years (Fig 10).

Anticoagulant-Related Hemorrhage

Anticoagulant-related hemorrhage occurred in 5 patients (0.9 per 100 patient-years) with two fatalities. Four of the five hemorrhagic events occurred in patients with SE-SE prostheses, with one event in a patient with BS-H valves. The SJM-SJM and H-H groups had significantly fewer thromboembolic and anticoagulant-related events than the other valve groups (Figs 11, 12; see Fig 6). The decreased incidence of anticoagulant-related hemorrhage in the H-H group by definition is going to be low because very few patients in that group were receiving warfarin.

Fig 9. Comparison of actuarial curves of freedom from thromboembolism (TE) in 89 hospital survivors of combined aortic and mitral valve replacement with five different combinations of substitute valves. (BS = Björk-Shiley [tilting-disc]; H = Hancock; SE = Starr-Edwards; SJM = St. Jude Medical.)

Fig 10. Comparison of actuarial curves of freedom from thromboembolism (TE) in 89 hospital survivors of combined aortic and mitral valve replacement with three different combinations of substitute valves: mechanical, bioprosthetic, and a combination of the two.

Valve-related late morbidity and mortality paralleled the incidence of total survival (Fig 13; see Fig 1). There was no difference in overall valve-related late morbidity and mortality between the dual bioprosthetic, dual mechanical, and combined valve replacement groups (Fig 14).

Sixty-nine patients took warfarin after operation: all patients in the SJM-SJM and BS-H groups, 33 of 34 in the SE-SE group, 12 of 14 patients in the SE-H group, and 4 of 19 patients in the H-H group. The patients with Starr-Edwards valves in place who did not take warfarin did so secondary to severe bleeding problems or noncompliance. The patients in the H-H group took warfarin because of atrial fibrillation or a history of strokes.

Comment

Simultaneous aortic and mitral valve replacement has been performed for many years, but, in almost all large

Fig 11. Comparison of actuarial curves of freedom from anticoagulant-related hemorrhage (ARH) in 89 hospital survivors of combined aortic and mitral valve replacement with five different combinations of substitute valves. Fig 12. Comparison of actuarial curves of freedom from anticoagulant-related hemorrhage (ARH) in 89 hospital survivors of combined aortic and mitral valve replacement with three different combinations of substitute valves: mechanical, bioprosthetic, and a combination of the two.

series of patients, the combination of a mechanical and a bioprosthetic valve is still reported (10% to 15%). The reasons for the combination are unclear. At the National Institutes of Health, it was thought that a bioprosthetic valve in the aortic position would not last as long as in the mitral position. Although the converse has turned out to be the case, that reasoning has certainly played a role in not inserting bioprosthetic valves in the aortic position but does not explain why a mechanical valve was not placed in the mitral position. There is no scientific basis for mixing prosthetic types unless some anatomical constraint noted at the time of operation necessitated a particular valve type, which should be a rare occurrence. Combining a mechanical and a bioprosthetic valve requires the patient to undergo long-term anticoagulation as

Fig 13. Comparison of actuarial curves of all valve-related mortality and morbidity (M+M) (freedom from death, reoperation, thromboembolism, and anticoagulant-related hemorrhage) in 89 hospital survivors of combined aortic and mitral valve replacement with five different combinations of substitute valves. (BS = Björk-Shiley [tilting-disc]; H = Hancock; SE = Starr-Edwards; SJM = St. Jude Medical.)

Fig 14. Comparison of actuarial curves of all valve-related mortality and morbidity (M+M) (freedom from death, reoperation, thromboembolism, and anticoagulant-related hemorrhage) in 89 hospital survivors of combined aortic and mitral valve replacement with three different combinations of substitute valves: mechanical, bioprosthetic, and a combination of the two.

well as a possible second operation for structural deterioration.

This study indicates that, during the first year after combined aortic and mitral valve replacement with any of the five substitute valves, decreased pulmonary arterial pressure, increased cardiac index, and improved functional class are achieved. These results show that there was no difference in overall survival or valve-related late morbidity or mortality between mechanical, bioprosthetic, and combined double-valve replacement at 15 years. There was, however, a lower reoperation rate in the groups with two mechanical valves than in the other two groups, and the higher the number of mechanical valves (excluding SJM-SJM), the higher the risk of combined thromboembolism and anticoagulant-related hemorrhage at 10 years. The groups with dual porcine valves had a higher rate of reoperation and a decreased combined incidence of thromboembolism and anticoagulant-related hemorrhage. The incidence of thromboembolism was the same in the three groups. Patients who received one or two Starr-Edwards prostheses had significantly higher rates of reoperation and combined thromboembolism and anticoagulant-related hemorrhage with a lower survival than those with other valve combinations.

Two previous reports from this institution have compared preoperative and postoperative hemodynamic data after combined aortic and mitral valve replacement. In the first report in 1967, Mason and associates [15] described a marked postoperative decrease in pulmonary arterial pressure and increase in cardiac output in the 12 patients studied. Melvin and associates [16] in 1973 analyzed preoperative and postoperative prognostic factors in 100 patients with combined aortic and mitral valve replacement, finding lower long-term survival in older patients and in those with elevated pulmonary arterial pressures, but no difference in terms of the types of valves that were placed. The operations in that study were performed

between 1963 and 1970, whereas the interval of study in the present group of patients was 1970 to 1989.

Several reports of late results of combined aortic and mitral valve replacement are available (Table 4), but most are not comparable with this study because of variance of inclusion criteria, duration and completeness of follow-up, and presentation of morbidity and mortality data. Armenti and associates [17] in 1987 reported results of combined aortic and mitral valve replacement with the SJM-SJM combination in 92 patients with a mean follow-up period of 2.8 years. Actuarial survival at 3 and 5 years was 76% and 62%, respectively. Linearized rates of thromboembolism and anticoagulant-related hemorrhage were 4.6%/year and 1.2%/year, and reoperation was performed at a rate of 2.1%/year. Thromboembolism was the most common complication after insertion of the SJM-SJM combination in that study. The absence of morbidity and mortality in our 10 patients with the SJM-SJM combination may be due in part to the small number of patients, the younger mean age at operation, the recent dates of operation and short follow-up period (mean, 2 years), and meticulous attention to anticoagulation regulation.

Bortolotti and associates [18] in 1987 reported late results after combined aortic and mitral valve replacement with dual Hancock bioprostheses in 55 patients with a mean follow-up of 5.7 years. Ten-year survival of hospital survivors was 54%, compared with 68% in our smaller group (14 patients) with dual Hancock bioprostheses. Thromboembolism occurred in 1.3%/year, compared with 3.2%/year in our group, and reoperation was performed in 3.5%/year, compared with 1.6%/year in our group. Bortolotti and associates [19] in 1988 published late results of simultaneous insertion of a mechanical aortic prosthesis and a porcine mitral bioprosthesis in 76 patients. Rates of thromboembolism, anticoagulant-related hemorrhage, and reoperation were higher than when dual bioprostheses were used.

Bortolotti and associates [20] in this journal in 1991 reported on the influence of type of prosthesis on late results after combined mitral and aortic valve replacement. Using 14 different valve combinations over 14 years, they concluded that there was no difference in survival, thromboembolism, or anticoagulant-related hemorrhage between mechanical, biological, or mixed replacements strategies. They also showed that the reoperation rate was lowest in the groups with dual mechanical valves as compared with the group with dual bioprosthetic valves or a combination of a mechanical and a bioprosthetic valve. Our data agree with these findings in that there was no difference in survival between groups, and the higher the number of bioprosthetic valves, the higher the reoperation rate. However, our data did show that the more mechanical valves that were used, the higher the incidence of anticoagulant-related hemorrhage, but this was largely influenced by the SE-SE group and the fact that patients with dual bioprosthetic valves are less likely to be anticoagulated.

Our data also support the continued practice of using a St. Jude Medical prosthesis in both positions when anticoagulation is not contraindicated. The patients with a

^a Hospital survivors or survival >30 days. ^b Present study.

ARH = anticoagulant-related hemorrhage; bpv = bioprosthetic valve; BS = Björk-Shiley (tilting-disc); FU = follow-up; H = Hancock; MH = Medtronic-Hall; mv = mechanical valve; SJM = St. Jude Medical; TE = thromboembolism.

bioprosthetic mitral valve and a mechanical aortic valve have the same long-term survival as those with dual mechanical or bioprosthetic valves but have a reoperation rate that is worse than the dual mechanical valve group and equal to the dual bioprosthetic valve group. The incidence of the combined thromboembolism and anticoagulant-related hemorrhage is higher than that of the dual bioprosthetic valve group but less than that of the dual mechanical valve group. The practice of combining a bioprosthesis and a mechanical prosthesis should be discouraged, as this combination imparts the disadvantages of both valve types and the advantages of neither, especially if the patient requires anticoagulation for reasons other than for a mechanical valve [21, 22]. Meticulous attention should be paid to regulation of anticoagulation as 60% of the thromboembolic and 80% of the anticoagulant-related hemorrhagic events occurred when the prothrombin time was subtherapeutic or supratherapeutic, respectively.

Open Mitral Commissurotomy: Fourteen- to Eighteen-Year Follow-up Clinical Study

Jose M. Herrera, MD, Jose L. Vega, MD, Jose M. Bernal, MD, Jose M. Rabasa, MD, and Jose M. Revuelta, MD

Cardiovascular Surgery, Hospital Universitario "Marqués de Valdecilla," Universidad de Cantabria, Santander, Spain

From May 1974 to December 1978, 159 patients with mitral stenosis underwent open mitral commissurotomy at our institution. Follow-up data were complete in 96.8%, with a mean follow-up of 13.7 years (range, 14 to 18 years). Preoperatively, most patients ($n = 94$) were in functional class III or IV. Valve calcification was found in 18 patients (11.3%), left atrial thrombosis was found in 21 (13.2%), and the subvalvular apparatus was affected in 105 (66%). When a residual insufficiency was detected during the operation, a mitral annuloplasty was performed ($n = 43$). There was one hospital death (0.6%) and 15 late deaths (9.5%). Actuarial survival at 15-year and 18-year follow-up is $89.4\% \pm 3\%$ and $75.2\% \pm 10.8\%$. Fifteen patients (9.7%) had a thromboembolic episode 1

to 189 months after operation (mean, 104.3 months). Eleven patients (7%) required reoperation 3 to 183 months after operation (mean, 110.1 months). Freedom from reoperation at 18-year follow-up was $91.9\% \pm 2.7\%$. Event-free actuarial survival at 15-year and 18-year follow-up was $73.4\% \pm 4.2\%$ and $54.3\% \pm 10.5\%$. Most patients ($n = 131$) are in class I or II. Open mitral commissurotomy represents a safe surgical alternative for treating mitral stenosis, allowing a complete removal of atrial thrombosis if present. This long-term follow-up clinical study encourages us to persist in this successful surgical repair of mitral stenosis.

(*Ann Thorac Surg* 1993;55:641-5)

Numerous reports have been published demonstrating the efficiency of closed mitral commissurotomy for the surgical treatment of pure mitral stenosis [1-5]. Different authors [6-8] have advocated routine use of the open technique as the method of choice. In 1980, controversy still remained about the best approach to mitral commissurotomy, so we published our early results in 163 consecutive patients with pure mitral stenosis who underwent open mitral commissurotomy (OMC) [9]. Currently, a new controversy has emerged regarding OMC versus percutaneous valvuloplasty. We here retrospectively analyzed the long-term follow-up in OMC with the same series of patients previously reported [9].

Material and Methods

From May 1974 to December 1978, 159 patients with pure mitral stenosis underwent OMC at our institution. Mean age was 41.5 years (range, 13 to 65 years), and 78% of the patients were female. Preoperatively 59% were in New York Heart Association functional class III or IV. Preoperative thromboembolic phenomena were recorded in 44 patients (27.8%). Nine had a previous closed mitral commissurotomy.

All patients had a preoperative hemodynamic study except 2 who required an emergency operation. Systolic pulmonary artery pressure ranged from 25 to 150 mm Hg

(mean, 45.7 mm Hg), the mitral gradient ranged from 8 to 32 mm Hg (mean, 17.2 mm Hg), the cardiac index ranged from 1.5 to $6.7 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ (mean, $2.8 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$), and the total pulmonary resistance ranged from 168 to 2,853 dynes $\cdot \text{s} \cdot \text{cm}^{-5}$ (mean, 563 dynes $\cdot \text{s} \cdot \text{cm}^{-5}$).

All the patients were operated on with conventional extracorporeal circulation using a bubble oxygenator, hypothermia, and, since 1977, coronary perfusion with a cold crystalloid cardioplegic solution. In every patient, after commissurotomy the valvular competence was tested by injecting blood from the extracorporeal pump through a left-vent cannula [10]. Calcification in the valve was found in 18 patients (11.3%) and left atrial thrombus in 21 patients (13.2%). The subvalvular apparatus was affected in 66% of the patients. The operative procedures were isolated commissurotomy in 51 patients; mitral commissurotomy and splitting of papillary muscles in 65; mitral commissurotomy and annuloplasty in 10; and mitral commissurotomy, splitting of papillary muscles, and annuloplasty in 33 patients. Open mitral commissurotomy was successfully performed in 116 patients (71.1%) with pure mitral stenosis. Mitral annuloplasty was performed using a Duran flexible ring in 36 patients, a Carpentier ring in 5 patients, and the Wooler technique in 2 patients. All patients with atrial fibrillation with preoperative thromboembolism or presence of atrial thrombus received long-term oral anticoagulant therapy. This was permanent in patients with giant left atrium or atrial thrombosis.

The follow-up was complete in 96.8% from January through July 1991 with an average of 13.7 years (range, 14

to 18 years). All elements of data collection were subjected to computer analysis. Chi-square test and Student's *t* test were used for analysis of significance. Survival and cumulative incidence curves were obtained by the actuarial method. Several preoperative factors were examined for their predictive value of the need for reoperation, late death, and postoperative functional class. These factors were age, preoperative functional class and pulmonary resistance, presence of atrial fibrillation, preoperative thromboembolism, presence of left atrial thrombus, mitral valve calcification, papillotomy, and annuloplasty.

Results

Hospital Mortality

A 60-year-old patient with severe pulmonary hypertension died 20 days postoperatively as a consequence of respiratory failure, being the only patient lost early after operation (0.6%).

Late Mortality

Late death occurred in 15 patients (9.5%) due to thromboembolism (*n* = 1), noncardiac causes (*n* = 2), sudden death (*n* = 1), and at home of unknown origin (*n* = 11).

Actuarial survival at 15-year and 18-year follow-up is $89.4\% \pm 3\%$ and $75.2\% \pm 10.8\%$, respectively (Fig 1).

Thromboembolism and Anticoagulant-Related Hemorrhage

Fifteen patients (9.7%) had thromboembolic episodes: 6 central with total recovery and 9 peripheral. Thromboembolic events occurred 1 to 189 months after operation (mean, 104.3 months). Four patients were in atrial fibrillation and none were anticoagulated when the event occurred. The actuarial freedom from thromboembolic events is $88.2\% \pm 3.2\%$ and $84.3\% \pm 4.9\%$ at 15-year and 18-year follow-up, respectively (Fig 2). Four of 24 patients (16.7%) receiving permanent anticoagulation had hemor-

MI + TI	1	MVR + TA	1
TI	1	TA	1

AS = aortic stenosis; CABG = coronary artery bypass grafting; CAD = coronary artery disease; MAVR = mitral and aortic valve replacement; MI = mitral insufficiency; MS = mitral stenosis; MVR = mitral valve replacement; Mixed ML = mixed mitral lesion; OMC = open mitral commissurotomy; TA = tricuspid annuloplasty; TI = tricuspid insufficiency.

rhagic complications: 3 minor external and 1 internal bleeding controlled by medical treatment.

Reoperations

Eleven patients (7%) required reoperation 3 to 183 months after operation (mean, 110.1 months). Causes of reoperation were structural deterioration in 9 patients (restenosis in 5, insufficiency in 2, and mixed mitral lesion in 2 patients), valve endocarditis in 1 patient, and severe tricuspid incompetence in 1 patient (Table 1).

Mitral commissurotomy was successfully performed at reoperation in 2 patients, and valve replacement was necessary in 8 patients (bioprosthesis in 3 and mechanical valve in 5). The remaining patient required Duran flexible ring annuloplasty. Concomitant aortic valve replacement was performed in 2 patients, tricuspid annuloplasty in 2, and coronary artery bypass grafting in 1 patient. Freedom from reoperation in this series is $91.9\% \pm 2.7\%$ and 88.4%

$\pm 4.3\%$ at 15-year and 18-year follow-up, respectively (Fig 3).

Event-free actuarial survival at 15-year and 18-year follow-up was $73.4\% \pm 4.2\%$ and $54.3\% \pm 10.5\%$, respectively (Fig 4). This incidence does not include nonrelated mitral valve reoperation ($n = 1$) and noncardiac deaths ($n = 2$).

Functional Class

Postoperatively, 60 of the surviving patients (41.6%) were asymptomatic, 71 patients (50%) in class II, 8 patients (5.6%) in class III, and 4 patients (2.8%) in class IV. Most patients in class III or IV ($n = 11$) underwent reoperation. Actually, only 1 patient remains in class III due to severe coronary artery disease.

Preoperative Risk Factors

As shown in Table 2, the age at the time of operation and the presence of atrial thrombosis were risk factors achieving significance ($p < 0.01$) for late mortality. Associated mitral annuloplasty represented a risk factor for postoperative thromboembolism ($p < 0.001$). Patients who died were older than the surviving patients (mean age, 50.4 years versus 38 years) and had a greater incidence of left atrial thrombosis (38.5% versus 10.3%).

Comment

As we previously reported with the same group of patients [9], OMC can be carried out with a low hospital mortality, similar to or lower than that of the closed mitral approach [1, 2, 11-14] and that of percutaneous mitral valvuloplasty [15]. The open technique allows the surgeon to work under direct vision, repair fused chordae tendineae and papillary muscles, debride the localized calcium nodules, and perform annuloplasty if required to control the residual insufficiency. Operative mitral valve competence was examined by injecting blood under pressure through the left ventricular apex, because in those early years transesophageal echocardiography was not

Fig 3. Actuarial curve of freedom from reoperation for any cause.

Fig 4. Event-free actuarial curve at 18-year follow-up.

available. The actuarial survival and freedom from valve-related reoperation at long-term follow-up, and the fact that a majority of patients are leading an active normal life (91.6% in class I or II), are similar to the data reported by other authors [11-13, 16]. We believe that the incidence of restenosis is intimately connected with the fusion of the subvalvular apparatus, so a complete repair is a crucial factor to produce a satisfactory long-term functional outcome.

Open mitral commissurotomy also allows the surgeon to visualize and remove left atrial thrombus, which was found in 13.2% of the patients in close relation to the presence of atrial fibrillation and previous thromboembolic episodes [9].

Statistical analysis of the clinical data has demonstrated that the age at the time of operation and the presence of left atrial thrombus represent risk factors for late mortality. When the incidence of thromboembolic episodes after OMC was studied for the different subgroups of patients, we found that of patients in atrial fibrillation ($n = 66$) only 4 patients (6%) had a thromboembolic event, compared with 11 patients (11.8%) in the group of patients in sinus

rhythm ($n = 93$). This controversial finding was probably due to the fact that most of the patients ($n = 9$) in sinus rhythm had a prosthetic annuloplasty ring to repair the mitral valve at the time of OMC. The presence of this prosthetic material in the left atrium could act as a trigger of thrombus formation. As shown in Table 2, the presence of the annuloplasty ring (10 of 15 patients) increased the incidence of postoperative thromboembolism with a high statistical significance ($p < 0.001$). Thromboembolism occurred in 2 patients (9.5%) with preoperative atrial thrombosis ($n = 21$), compared with 13 patients (9.4%) without atrial thrombosis ($n = 138$; $p > 0.05$).

All patients with preoperative thromboembolism and those with atrial thrombus ($n = 52$) received permanent oral anticoagulant therapy after operation. Six thromboembolic episodes occurred in this group of patients and nine events in the remaining 107 patients (11.5% versus 8.4%; $p > 0.05$).

Presence of localized valve calcification and subvalvular apparatus pathology were not determinant in the long-term results, as the group of patients with unsatisfactory valve anatomy at operation had an outcome similar to that

Table 2. Risk Factors in Open Mitral Commissurotomy

Risk Factor	Death (n = 13)	Reoperation (n = 11)	Thromboembolism (n = 15)
Age (y)	50.4 ^a	39.4	41.6
NYHA class III or IV	10 (76.9%)	6 (54.5%)	10 (66.7%)
Atrial fibrillation	9 (69.2%)	5 (45.4%)	4 (26.7%)
Preoperative thromboembolism	5 (38.5%)	1 (9.1%)	6 (40%)
Pulmonary resistance (dynes · s · cm ⁻⁵)	603	640	476
Atrial thrombosis	5 ^b (38.5%)	1 (9.1%)	2 (13.3%)
Papillotomy (subvalvular disease)	8 (61.5%)	7 (63.6%)	10 (66.7%)

NYHA = New York Heart Association.

of those who did not. Associated mitral valve surgical repair, particularly in patients with residual incompetence after OMC, was important to assure long-term satisfactory results.

In conclusion, OMC with concomitant mitral valve operation to repair the associated lesions represents a stable and safe surgical treatment with a low hospital and late mortality and a low incidence of long-term valve-related complications requiring reoperation. Most patients are asymptomatic 14 to 18 years after operation, leading an active normal life.

Pulmonary Artery Size and Clinical Outcome After the Modified Fontan Operation

Christopher J. Knott-Craig, MD, Paul R. Julsrud, MD, Hartzell V. Schaff, MD, Francisco J. Puga, MD, and Gordon K. Danielson, MD

Division of Thoracic and Cardiovascular Surgery and Department of Radiology, Mayo Clinic and Mayo Foundation, Rochester, Minnesota

The maximum cross-sectional area of the central pulmonary arteries indexed to the body surface area (pulmonary artery index [PAI]) was measured preoperatively from angiograms in 173 patients evaluated for a Fontan-type operation between 1981 and June 1989. Of these, 34 patients underwent another palliative procedure, 8 primarily on the basis of small pulmonary arteries (PAI, 106 to 167 mm²/m²). The mean PAI of this group was significantly smaller than the mean PAI of the remaining 139 patients who underwent a Fontan operation (136 ± 20 versus 310 ± 113 mm²/m²) ($p < 0.001$). The patients who underwent a Fontan operation were evaluated according to three overlapping end points: (1) hospital death or takedown of repair (12.2%), (2) early failure (cumulative death or takedown of repair within 6 months of operation) (16.5%), and (3) early failure or persistent effusions (33.8%). With regard to these end points, no significant difference in pulmonary artery size could be found between patients having a favorable or unfavorable

outcome. However, among a low-risk subset of 30 patients with tricuspid atresia, those with "early failure or persistent effusions" had significantly smaller pulmonary arteries than those with a good outcome (PAI, 185 ± 47 versus 276 ± 83 mm²/m²) ($p < 0.01$). The postoperative transpulmonary gradient of the 8 patients with the smallest pulmonary arteries who underwent a Fontan operation (all PAIs < 170 mm²/m²) was significantly greater than that of the rest of the study group (9.88 ± 2.3 versus 8.13 ± 2.3 mm Hg) ($p < 0.04$). Small pulmonary arteries, in otherwise good-risk patients, are associated with increased risk of "early failure or persistent effusions" after the Fontan operation. The lowest PAI compatible with success remains unknown. To obtain a more comprehensive assessment of a successful outcome, we suggest that evaluation of patients after a Fontan operation include end points other than hospital death.

(*Ann Thorac Surg* 1993;55:646-51)

Small pulmonary arteries have been considered a contraindication to the Fontan-type operation since the first successful case was reported in 1971 [1]. Subsequently published guidelines for selection criteria have reinforced the belief that for a successful outcome the pulmonary arteries must be of sufficient size to allow unrestricted flow [2, 3]. This has been defined as a McGoon ratio of 1.8 or greater [4], which is equivalent to a pulmonary artery cross-sectional area index (or pulmonary artery index [PAI]) of more than 200 mm²/m² [Kirklin JW; personal communication, Feb 1990].

In recent years, however, surgeons have extended the modified Fontan procedure to patients who do not satisfy the traditional selection criteria with remarkable success [5-8]. This policy has renewed interest in the influence of central pulmonary artery size on clinical outcome after a Fontan operation, and in identifying the smallest pulmonary arteries consistently compatible with a good clinical outcome. From our data with *intraoperative* measurement of pulmonary artery size, Girod and associates [9] reported successful outcome in a patient with a PAI as low as 188 mm²/m². Bridges and colleagues [10], using preop-

erative echocardiographic measurements, recently reported operative survival in patients with a preoperative PAI less than 100 mm²/m², in whom the pulmonary arteries were enlarged at operation.

These reports prompted us to review our data on pulmonary artery size measured and recorded preoperatively since 1981. Our goal was to further define the relationship between pulmonary artery size and clinical outcome including serious nonfatal complications after the modified Fontan operation.

Material and Methods

Study Design

Between 1981 and June 1989, 173 patients in whom both central pulmonary arteries could be accurately measured from preoperative angiographic studies were considered for a Fontan operation at our institution. Thirty-four patients (19.7%) were considered unsuitable for a Fontan procedure, and in most of these an alternative palliative or preparatory procedure was performed. The available data on these patients were reviewed to determine whether pulmonary artery size influenced the decision not to perform a Fontan procedure.

The study group comprises the remaining 139 patients who underwent a modified Fontan operation. Their rele-

Table 1. Risk Factors for Patients Undergoing the Fontan Operation (n = 139)

Factor	Mean $\pm$ SD or Percentage	Median	Range
Age (y)	11 $\pm$ 7	10	1-42
Previous procedures (No.)	1.5 $\pm$ 1	1	0-6
Mean PA pressure (mm Hg)	20 $\pm$ 10	18	2-73
Q _p /Q _s	1.6 $\pm$ 1.2	1.1	0.2-6
PARI (U $\cdot$ m ²)	2.0 $\pm$ 1.1	1.85	0.2-4.5
VEDP (mm Hg)	14.4 $\pm$ 4.5	14	6-28
Ejection fraction	0.56 $\pm$ 0.10	0.57	0.35-0.82
LPA repair	23% (n = 33)		
RPA repair	17% (n = 24)		
AVV repair	7% (n = 10)		
AVV replacement	2.1% (n = 3)		

AVV = atrioventricular valve; LPA = left pulmonary artery; PA = pulmonary artery; PARI = pulmonary arteriolar resistance index; Q_p/Q_s = pulmonary to systemic shunt; RPA = right pulmonary artery; VEDP = ventricular end-diastolic pressure.

vant data were entered into a single data base, which is summarized in Table 1. These data are not significantly different from those of the remaining 399 patients undergoing a Fontan operation during the same period. There were 85 male and 54 female patients, ranging in age from 1 to 42 years (median, 10 years). The study group was analyzed using three overlapping criteria for a poor clinical result in an attempt to determine whether pulmonary artery size influenced early mortality or morbidity. The patients' records were reviewed in December 1989, at which time 6-month follow-up data were available on all the patients.

From the study group, a low-risk subgroup of patients was identified (n = 30), and the same analyses were done. The criteria for selection were age 4 years or older, pulmonary arteriolar resistance index less than 2.0 U $\cdot$ m², and no significant atrioventricular valve regurgitation. These patients all had tricuspid atresia and physiology generally favorable for a Fontan operation.

The following preoperative risk factors for hospital death/takedown were analyzed: age at operation, ventricular end-diastolic pressure, pulmonary artery pressure, pulmonary arteriolar resistance index, number of previous operations, ventricular ejection fraction, pulmonary artery size, significant AV valve regurgitation, distorted pulmonary arteries, pathological lesion, and postrepair central venous pressure.

Definitions of Outcome

Hospital death or takedown is defined as death or takedown of the Fontan repair within 30 days of operation or before discharge from hospital. *Early failure* is defined as the cumulative incidence of mortality and takedown of the repair within 6 months (180 days) of operation (including hospital death or takedown). *Failure/effusions* is defined as the cumulative incidence of mortality and takedown of repair within 6 months of operation or prolonged pericardial/pleural effusions, ie, effusions persisting 18 or more

days during the postoperative period or requiring a pericardiectomy or pleurodesis within 6 months of the Fontan operation.

Measurement of Pulmonary Artery Size

All pulmonary angiograms were interpreted at the time of the preoperative evaluation by one cardiac radiologist (P.R.J.). Both pulmonary arteries were measured at the upper lobe bifurcations during that phase of the cardiac cycle associated with maximum size. (This differs slightly from the technique described by Nakata and associates [11], who defined pulmonary artery size in terms of the average of the measurements made during systole and diastole.) The measured diameters of the pulmonary arteries were corrected for magnification, and the cross-sectional areas were calculated from the corrected pulmonary artery diameter size; the areas were summed and divided by the patient's body surface area to yield the PAI, which is expressed as square millimeters per square meter.

Surgical Technique

Our surgical technique reflects the experience obtained in the 703 Fontan operations performed at this institution between October 1973 and December 1989 [12]. Operations were usually performed under deep hypothermia (20° to 25°C) facilitated by periods of low-flow perfusion (0.5 to 1.5 L $\cdot$ min⁻¹ $\cdot$ m⁻²) or circulatory arrest as necessary. Myocardial protection was achieved with intermittent cold blood or crystalloid cardioplegia and topical hypothermia. Direct atriopulmonary connection has remained the preferred anastomosis for tricuspid atresia and double-inlet left ventricle. In most patients with univentricular heart, the systemic and pulmonary venous drainage were partitioned in such a way that the coronary sinus drained into the pulmonary venous side of the atrial baffle, but no special techniques were employed to achieve this if the anatomy was unfavorable.

Perioperative Management

Intraoperatively the patients were well transfused and usually left the operating room with a central venous pressure around 16 to 18 mm Hg. Dopamine and sodium nitroprusside were commenced in dosages of 4 μ g $\cdot$ kg⁻¹ $\cdot$ min⁻¹ and 1 μ g $\cdot$ kg⁻¹ $\cdot$ min⁻¹, respectively, just before weaning from cardiopulmonary bypass, and this ratio was generally maintained in the early postoperative period. During the first 2 days after operation, chest tube drainage was replaced with colloid solutions, blood, or both to maintain an adequate cardiac output with correspondingly less inotropic support.

Mechanical ventilation was continued for an average of 3 to 4 days postoperatively, and no attempt was made to withdraw respiratory support until the patients' hemodynamic and respiratory parameters were stable. Positive end-expiratory pressure of 3 to 5 mm Hg was maintained while the patients were on the ventilator, with the head of the bed elevated about 10 to 15 degrees.

Because transient venous congestion of the viscera often delayed the return of intestinal function [13], we

frequently initiated parenteral alimentation early postoperatively and continued this until the patient was taking adequate nutrition by mouth.

Methods of Analysis

Wilcoxon rank-sum analysis was used to compare continuous variables. All *t* tests are two-tailed, and a *p* value of 0.05 or less was considered significant. Discrete variables were analyzed with χ^2 tables using Yates' correction. Data are represented as mean $\pm$ standard deviation, followed by the median value in parenthesis where applicable.

Results

Influence of Pulmonary Artery Size on Patient Selection

Of the 173 patients who were evaluated for a Fontan procedure, 34 were considered unsuitable for this operation; in 8 of these patients the decision not to perform a Fontan-type operation was made predominantly on the basis of small pulmonary artery size. Their PAIs ranged from 106 to 167 mm²/m², and their mean PAI was significantly smaller than that of the 139 patients who underwent a Fontan operation: 136 $\pm$ 20 versus 310 $\pm$ 113 mm²/m² (*p* < 0.001). The subjective preoperative evaluation was that the pulmonary arteries were too small for a Fontan operation.

In retrospect, however, 8 patients with pulmonary artery indices in the same range did undergo a Fontan operation (PAI = 108, 116, 139, 140, 145, 150, 158, and 168 mm²/m²). In 2, pulmonary artery augmentation was indeed extended beyond the bifurcation, ie, the point of measurement of the PAI. With one exception, these were all considered to be "low-risk" candidates except for their small pulmonary arteries: 6 had tricuspid atresia, 1 had double-inlet left ventricle, and 1 had mitral atresia. The patient with mitral atresia and the smallest PAI (108 mm²/m²) died 4 years after his modified Fontan operation while awaiting heart transplantation after eventual takedown of his Fontan repair. In the interim he had undergone reconstruction of the right pulmonary artery and systemic atrioventricular valve replacement, and a pulmonary angiogram shortly before his death (Fig 1) demonstrated that the pulmonary arteries had not grown significantly since his first operation (PAI, 108 mm²/m² versus 107 mm²/m²). The other 7 patients were all alive and well at last follow-up 8 months and 2, 4, 5, 5, 6, and 8 years after operation, although 3 had persistent effusions and 3 had low cardiac output in the early postoperative period. The mean transpulmonary gradient (central venous pressure - left atrial pressure), measured at the end of the operation of these 8 patients, was significantly higher (9.88 $\pm$ 2.3 mm Hg; median, 11 mm Hg) than that of the rest of the patients who underwent a Fontan operation (8.13 $\pm$ 2.3 mm Hg; median, 8 mm Hg) (*p* < 0.04). The highest preoperatively measured pulmonary arteriolar resistance index among these 8 patients was 2.4 U $\cdot$ m²; 5 of the 8 patients are included among the low-risk subgroup of tricuspid atresia patients.

There was no significant difference in preoperative PAI between those who did and did not have pulmonary

Fig 1. Angiogram obtained 5 days before takedown of the modified Fontan repair. Note the small pulmonary arteries, which preoperatively were estimated to have a pulmonary artery index of 108 mm²/m². Note the left-sided morphologically right atrium, and the prosthetic atrioventricular valve. Arrow indicates the small interatrial right-to-left shunt demonstrated by contrast material entering the pulmonary venous atrium from the dilated systemic venous atrium.

artery augmentation at the time of their operation. This similarity in preoperative PAI (Fig 2) suggests that the measurements were generally made beyond the point of the reconstruction, and that the PAIs were not augmented by the procedure. If the PAIs were clearly smaller in the patients in whom pulmonary artery reconstruction was done, then it might well be argued that the PAI measurements were not made distal to the most distal point of repair. Although generally true, this inference is inaccurate in at least 2 patients with small pulmonary arteries in whom the reconstruction extended beyond the bifurcation.

Clinical Outcome According to Defined End Points

The hospital mortality for the study group (*n* = 139) was 11.6%, which includes 3 patients who did not survive

Fig 2. Comparison of preoperative pulmonary artery (PA) index according to outcome in patients with and without pulmonary artery reconstruction. (dt/tkdn = death/takedown; earl/fail = early failure; fail/eff = early failure or persistent effusions.)

Fig 3. Results of Fontan operation in patients with tricuspid atresia (TA) ($n = 46$), double-inlet ventricle (DIV) ($n = 38$), complex pathology ($n = 55$), and as a single group (ALL) ($n = 139$) according to three end points: death/takedown (dth/tkdown), early failure (early fail), and early failure or persistent effusions (fail/eff).

takedown of their repair. One additional patient is alive after early takedown of his Fontan anastomosis, yielding a combined incidence of hospital mortality and takedown of 12.2%. Early failure (cumulative 6-month mortality and takedown incidence) was 16.5%. In addition, 17.3% of patients had prolonged effusions according to our definition. The combined failure/effusion rate was therefore 33.8% ($16.5\% \pm 17.3\%$). Separated into previously defined pathological groups, the results are summarized in Figure 3.

Of the risk factors for hospital death/takedown that were analyzed univariately, only early age ($p < 0.01$), increased pulmonary arteriolar resistance index ($p < 0.05$), and postrepair central venous pressure greater than 20 mm Hg ($p < 0.02$) reached significance. In this series neither pathological lesion nor pulmonary artery size was a significant risk factor for hospital mortality or takedown. Most patients, however, had multiple risk factors, making interpretation of the data difficult (see Table 1); in this regard, only 4 patients satisfied all 10 of the initial selection criteria [3]. Nonoverlapping missing data precluded any meaningful multivariate analysis of risk factors for death or takedown.

The distribution of PAIs among all patients having a "good outcome" after the Fontan operation varied widely from relatively small ($108 \text{ mm}^2/\text{m}^2$) to very large ($>550 \text{ mm}^2/\text{m}^2$). Although there was considerable overlap, the distribution of PAIs by intervals for all three "poor-outcome" end points was skewed to the left (Fig 4), suggesting that patients with smaller PAIs generally fared less well than patients with larger PAIs.

Outcome in Low-Risk Patients

Using our analyses and other published risk factors for hospital mortality [3, 4, 5, 7, 12, 14-16] we identified a low-risk subset of patients with tricuspid atresia. All patients in this subset satisfied at least three of ten of the original selection criteria [3]. By analyzing this low-risk subset of patients, we attempted to more clearly establish

Fig 4. Relationship of pulmonary artery (PA) index to defined end points by intervals for study group ($n = 139$). (dt/tkdown = death/takedown; early fail = early failure; fail/eff = early failure or persistent effusions.)

whether central pulmonary artery size in any way influenced their clinical outcome in terms of increased morbidity or mortality.

Within this subset ($n = 30$) the incidence of death/takedown was 3.3%, early failure occurred in 6.6%, and failure/effusions was identified in 20%, compared with 15.6%, 19.3%, and 37.6%, respectively, for the rest of the study group. Within this subgroup, the pulmonary artery size of those patients having failure/effusions was $185 \pm 47 \text{ mm}^2/\text{m}^2$ compared with $276 \pm 82 \text{ mm}^2/\text{m}^2$ in those having a good result ($p < 0.01$) (Fig 5). Furthermore, patients with a PAI less than $250 \text{ mm}^2/\text{m}^2$ had a failure/effusion rate of 43%, whereas those with larger pulmonary arteries without exception all survived with an uncomplicated postoperative course in terms of persistent or recurrent pleural and pericardial effusions ($p < 0.01$). The only patient who died in the hospital had a PAI of $210 \text{ mm}^2/\text{m}^2$, and the only other patient who died within 6 months of operation had a PAI of $198 \text{ mm}^2/\text{m}^2$.

Comment

End Points

Traditionally hospital discharge has been the end point selected to reflect early outcome after cardiac surgical procedures. We have been concerned, however, that this may not adequately reflect success after the Fontan procedure, as a small proportion of patients who survive their initial hospitalization period die within a few months or suffer debilitating complications of fluid retention, often requiring repeated admissions for pleuropericardial effusions or ascites. To address this aspect we defined the end points early failure and failure/effusions. Use of the 6-month postoperative interval for assessing early failure is supported by the collective experience of Fontan and Kirklin [14, 15], who noted that the early-phase hazard function for mortality after the Fontan procedure greatly diminishes after this interval.

The period of 18 days or more that was considered excessive for postoperative effusions was arbitrarily selected before the data were collected and the analyses done.

Overall Results

Patients referred for consideration of a Fontan procedure have already been preselected by their referring physicians on the basis of established selection criteria. Despite this bias, 19.7% of our referrals were thought unsuitable for a Fontan-type repair, and about a quarter of these were disqualified primarily on the basis of pulmonary artery anatomy. The central pulmonary arteries of these patients were clearly smaller than the average of those who underwent a Fontan operation; however, an equal number of patients with similarly small pulmonary arteries (PAI range, 110 to 170 mm²/m²) were accepted for a one-ventricle repair, and all survived the first 6 months after operation. Their postoperative courses were generally more stormy though, and of the 8 patients 3 had low cardiac output needing prolonged inotropic support postoperatively and 3 had prolonged pleural effusions (up to 43 days postoperatively). With one exception (a patient with mitral atresia and a PAI of 108 mm²/m² who died 4 years later despite repeated operation in the interim), all these patients had less complex anatomy (6 had tricuspid atresia, 1 had double-inlet left ventricle), and 5 were identified as low-risk patients in terms of our study design. The transpulmonary gradients in these patients were also significantly greater than the rest of the study group, and smaller pulmonary artery size probably influenced these circumstances.

When we analyzed the 139 patients in the study group who underwent a Fontan procedure, we could find no statistically significant influence exercised by pulmonary artery size according to the end points defined (see Fig 4). This may reflect the complexity of this patient population rather than a relative lack of significance of pulmonary artery size [4, 13, 17, 18]; in the low-risk subset of patients with tricuspid atresia, smaller pulmonary arteries were clearly associated with a higher probability of failure/effusions ($p < 0.01$) (see Fig 5). A PAI less than 250

mm²/m² was able to predict this end point with reasonable accuracy ($p < 0.01$), supporting the similar findings of others [4, 11]. In this instance failure/effusions reflects predominantly increased morbidity in the form of persistent or recurrent effusions (4 of the 6 patients), although the 2 patients in this low-risk group ($n = 30$) who died within 6 months of their operation both had PAIs less than 250 mm²/m² (198 and 210 mm²/m²).

Although it is clear that the major area of resistance to flow across the pulmonary bed is at the arteriolar level [19], small pulmonary arteries also contribute to this resistance. This has been established in complete repair of tetralogy of Fallot with hypoplastic pulmonary arteries [19, 20], in which correction has been advised only if the Nakata pulmonary artery index exceeds 100 mm²/m² [11]. It is unlikely, therefore, that a Fontan operation, in which there is no ventricle driving the pulmonary circulation, can succeed in the presence of pulmonary arteries that have a PAI of 100 mm²/m² or less, equivalent to a McGoon ratio of 1.2 [Kirklin JW; personal communication, Feb 1990]. The preoperative echocardiographic data of Bridges and associates [10], indicating success with the Fontan procedure in a patient with a PAI of 48 mm²/m², were not supported by similar intraoperative or postoperative measurements, and pulmonary artery augmentation probably contributed significantly to the postoperative size of the pulmonary arteries. When pulmonary artery augmentation accompanies the Fontan operation, the validity of the preoperative measurement depends on the site that the measurements are made, ie, the measurement should be made distal to the site of expected augmentation. For this, it may be necessary to measure the branch pulmonary arteries rather than the distal pulmonary arteries. Similarly, a comparison of preoperative data and intraoperative measurements may not be valid, as the former may underestimate the pulmonary artery size, particularly if the pulmonary blood flow is reduced [21]. Hence relating the observations in this study to our previously published intraoperative data [9] may be misleading.

Data from this analysis support the data of Fontan and associates [4] and others [11, 17, 18] that small preoperative pulmonary artery size is associated with a higher mortality and morbidity after the Fontan operation in low-risk patients, even though individual predictions cannot be made. Although many otherwise low-risk patients with PAIs in the range 120 to 170 mm²/m² may receive acceptable palliation from their Fontan operation in the short term, as evident from this study, we remain reluctant to perform a Fontan operation in general if the PAI is less than 170 to 180 mm²/m². In these circumstances we still prefer to encourage growth of the pulmonary arteries by constructing a generous central shunt, and reevaluate the patient 6 months to a year later.

We wish to thank Mr Duane M. Ilstrup from the Section of Biostatistics for his advice in the preparation of the statistical analyses.

Platelet Function in Cardiac Surgery: Influence of Temperature and Aprotinin

Joachim Boldt, MD, Christoph Knothe, MD, Bernfried Zickmann, MD, Sabine Bill, Friedhelm Dapper, MD, and Gunter Hempelmann, MD

Department of Anesthesiology and Intensive Care Medicine and Department of Cardiovascular Surgery, Justus-Liebig-University, Giessen, Germany

Hypothermic cardiopulmonary bypass (CPB) has been associated with both coagulation defects and hemorrhage. The influence of temperature on platelet function and the benefits of aprotinin in this situation were studied in 60 patients undergoing elective aortocoronary bypass grafting. The patients were randomly divided into four groups (15 patients per group): group 1, normothermic CPB (nasopharyngeal temperature $> 34^{\circ}\text{C}$); group 2, normothermic bypass and administration of high-dose aprotinin (2 million IU before CPB, 500,000 IU/h until the end of the operation, and 2 million IU added to the prime); group 3, hypothermic CPB (nasopharyngeal temperature $< 28^{\circ}\text{C}$); and group 4, hypothermic CPB and aprotinin. Platelet function was evaluated by aggregometry (turbidimetric technique), and aggregation was induced by adenosine diphosphate (1 and 2 $\mu\text{mol/L}$), collagen (4 $\mu\text{g/L}$), and epinephrine (25 $\mu\text{mol/L}$) before, during, and after CPB into the first postoperative day. Starting from comparable baseline values, maximum platelet aggregation and maximum gradient of platelet aggregation were significantly most reduced af-

ter CPB in group 3 (hypothermic CPB without aprotinin) (ranging from -30% to -53% relative to baseline values). In comparison with the other groups, platelet function in this group also recovered less quickly in the later postbypass period. Hypothermic CPB with aprotinin resulted in less-altered platelet function than hypothermic CPB without aprotinin. Platelet aggregation in aprotinin-treated patients was comparable overall with that in patients undergoing normothermic CPB. On the first postoperative day, aggregation variables had returned to or exceeded baseline values. Blood loss on the first postoperative day was significantly higher in group 3 ($680 \pm 220 \text{ mL}$) than in the other groups, and need for homologous blood and fresh frozen plasma was also most pronounced in these patients (6 units of packed red cells and 4 units of fresh frozen plasma). We conclude that aprotinin blunted the negative effects of hypothermic CPB on platelet function but failed to have any beneficial effects in patients undergoing normothermic CPB.

(*Ann Thorac Surg* 1993;55:652-8)

Approximately 10% to 20% of patients undergoing cardiac surgical procedures exhibit inadequate hemostasis, which varies in duration and severity. These patients often require treatment with homologous blood or blood products [1], and approximately 3% will need reexploration [2]. Therefore, various pharmacological and nonpharmacological interventions to reduce blood loss and need for homologous blood have been used, including asanguineous prime, predonation of autologous blood, and blood salvaging systems such as the Cell Saver (Haemonetics, Braintree, MA) or hemofiltration devices [3, 4]. In recent years, interest has focused on pharmacological manipulations to achieve hemostasis [5, 6]. The proteinase inhibitor aprotinin appears the most promising; several studies [7-10] have reported beneficial effects of aprotinin on reducing blood loss and homologous blood requirements.

Defects in platelet function are considered very important in postbypass hemorrhage [11-14]. Factors that con-

tribute to acquired platelet abnormalities include shear stress, blood gas interaction, heparin sodium and protamine sulfate, and interaction of platelets with the non-endothelial surfaces of the cardiopulmonary bypass (CPB) system [15]. Moreover, it is well established that platelet dysfunction can be induced by hypothermia [16]. Temperature-dependent morphological alterations include changes in the platelet membrane and its function [17].

The aim of this study was to investigate the influence of hypothermic CPB on platelet function and the possible benefits of high-dose aprotinin in patients undergoing a cardiac operation.

Material and Methods

Sixty consecutive male patients scheduled for elective aortocoronary bypass grafting were studied. Informed consent was obtained from all patients according to the protocol of the ethic study committee of the hospital. In all patients, a left internal mammary artery graft was used in addition to saphenous vein grafting. Inclusion criteria were disease of four or more vessels and an expected bypass time of longer than 80 minutes. Exclusion criteria were preoperative coagulation disorders, concomitant

valvular diseases, and medication with aspirin or other cyclooxygenase inhibitors within the last 10 days before operation.

The patients who met the criteria were prospectively randomized into four groups (15 patients per group):

Group 1: normothermic CPB (nasopharyngeal temperature $> 34^{\circ}\text{C}$)

Group 2: normothermic CPB and administration of high-dose aprotinin (2 million IU after induction of anesthesia, 500,000 IU/h until the end of the operation, and 2 million IU added to the prime)

Group 3: hypothermic CPB (nasopharyngeal temperature $< 28^{\circ}\text{C}$)

Group 4: hypothermic CPB and aprotinin

Anesthesia and Cardiopulmonary Bypass

Induction and maintenance of anesthesia were comparable for all groups and consisted of weight-related doses of fentanyl, pancuronium bromide, and midazolam hydrochloride. The patients remained on controlled mechanical ventilation for at least 5 hours after the operation.

Five minutes before initiation of CPB, 300 IU/kg of bovine lung heparin was administered to achieve anticoagulation. Bypass was carried out with a nonpulsatile pump and a membrane oxygenator (Sorin 41; Sorin, Torino, Italy). The circuit was primed with 1,000 mL of Ringer's solution, 1,000 mL of dextrose (5%), and 250 mL of human albumin (5%) in all groups as well as aprotinin in groups 2 and 4. In all groups, a perfusion flow of $2.4 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ was maintained for the entire bypass period. Blood was returned to the circuit using a two-stage cannula (monoatrial cannulation technique). For myocardial preservation, 1,000 mL of cardioplegic solution (Bretschneider) was infused.

Within 20 minutes after the start of CPB, the blood in the circuit was concentrated by a hemofiltration device (HF-80; Fresenius, Bad Homburg, Germany) to adjust the hemoglobin level between 80 and 90 g/L (8 and 9 g/dL) (hematocrit, 0.22 to 0.25). Later during CPB, Ringer's solution was added to the circuit when the hemoglobin level was greater than 70 g/L (7 g/dL) (hematocrit < 0.20); packed red cells were given when the hemoglobin level was lower. Patients in groups 2 and 4 were cooled by both surface cooling and the CPB system. Esophageal temperature, rectal temperature, and blood temperature in the oxygenator were measured continuously.

During weaning from CPB, as much pump blood was infused as necessary to keep the pulmonary capillary wedge pressure between 10 and 12 mm Hg. After weaning from CPB was completed, the residual blood in the circuit was salvaged by the hemofiltration device, and this autologous blood was retransfused until the end of the operation. Protamine sulfate was given in the same dose as the initial heparin dose to reverse the heparin effects. All patients were operated on by the same surgical team, which was blinded to the groups.

Data Points and Measured Variables

Arterial blood samples were taken after induction of anesthesia (baseline values), 20 minutes after the start of

CPB (after completion of hemoconcentration by hemofiltration), after weaning from bypass (before injection of protamine), at the end of the operation, 5 hours after the end of the operation, and on the morning of the first postoperative day.

Platelet aggregation was studied using the turbidimetric method [18] and a double-channel APACT aggregometer (Labor, Ahrensburg, Germany). Before aggregometry, platelet count was adjusted to approximately $150 \times 10^9/\text{L}$ ($150,000/\mu\text{L}$). Platelet aggregation was induced by adenosine diphosphate (1.0 and $2.0 \mu\text{mol/L}$), collagen ($4 \mu\text{g/mL}$), epinephrine ($25 \mu\text{mol/L}$), and NaCl (control). The maximum increase in light transmission after addition of the aggregating agent was defined as maximum platelet aggregation (percent increase). The maximum increase per minute was defined as maximum gradient of platelet aggregation (percent increase per minute). All measurements were carried out in duplicate. In addition, hemoglobin, hematocrit, platelet count, and activated clotting time were measured.

To maintain stable hemodynamics, albumin (5%) was given postoperatively (when pulmonary capillary wedge pressure was lower than 7 mm Hg and cardiac index was less than $2.30 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$). Packed red cells were given when the hemoglobin level was less than 90 g/L (9 g/dL) (hematocrit < 0.25). All volume therapy was indicated by anesthesiologists and intensivists who were not involved in the study and were blinded to the patient groups. Blood loss was calculated from intraoperative suction and chest tube drainage in the intensive care unit. Use of homologous blood and blood products (platelets or fresh frozen plasma) was also documented.

Statistical Analysis

Power analysis was carried out before starting the study to determine the number of patients necessary to protect from type II errors in the statistical interpretation. The mean $\pm$ the standard deviation was calculated for each variable. For statistical interpretation, one- and two-factor analyses of variance (including multivariate analysis of variance and the Scheffé test) were used. Percent changes from baseline were calculated for all aggregation variables. The χ^2 test was used to analyze differences in homologous blood use. A p value of less than 0.05 was considered significant.

Results

Biometric data and CPB data were comparable for the four groups (Table 1). Fluid balance during CPB (input and output) was significantly higher in the two groups undergoing hypothermic CPB than in the normothermic CPB groups. Blood loss was significantly highest in group 3 (hypothermia without aprotinin) (Fig 1), and the need for homologous blood (6 units of packed red cells) and blood derivatives (4 units of fresh frozen plasma) was also highest in these patients (see Table 1).

The degree of hemodilution (hematocrit) and the platelet count did not differ between groups during the entire study period (Table 2).

Table 1. Biometric and Cardiopulmonary Bypass Data^a

Variable	Normothermia	Normothermia + Aprotinin	Hypothermia	Hypothermia + Aprotinin
Age (y)	61.5 ± 6.0	63.5 ± 8.8	62.4 ± 5.0	64.1 ± 7.1
Weight (kg)	77.5 ± 8.7	78.2 ± 10.1	79.4 ± 9.6	78.3 ± 11.1
CPB (min)	99.6 ± 20.1	96.8 ± 27.1	103.1 ± 25.5	107.1 ± 20.9
Aortic cross-clamping (min)	58.6 ± 16.7	59.1 ± 17.1	63.2 ± 15.8	65.2 ± 16.2
Fluid balance during CPB (mL)	+670 ± 350	+420 ± 380	+1,120 ± 610 ^b	+1,020 ± 660 ^b
Lowest temperature (°C)				
Rectal	35.0 ± 0.4	34.8 ± 0.4	27.2 ± 0.3	27.1 ± 0.5
Nasopharyngeal	34.9 ± 0.2	34.7 ± 0.2	25.3 ± 1.0	25.7 ± 1.4

PRC	2	3	6 ^b	2
FFP	0	0	4 ^b	0

^a Where applicable, data are shown as the mean ± the standard deviation.^b Significance: $p < 0.05$ compared with the other groups.

CPB = cardiopulmonary bypass; FFP = fresh frozen plasma; PRC = packed red cells.

At baseline, all aggregation variables were comparable in the four groups (Figs 2-5). Cardiopulmonary bypass resulted in reduced maximum platelet aggregation and maximum gradient of platelet aggregation for all inducers. Aprotinin was without beneficial effect on platelet aggregometry in patients having normothermic CPB. Overall, alterations in platelet aggregometry were significantly most pronounced in the patients undergoing hypothermic CPB without aprotinin (group 3) (ranging from -30% to -53% relative to baseline values). When hypothermia was used in combination with aprotinin (group 4), aggregation was significantly less compromised than in group 3. Both maximum platelet aggregation and maximum gradient of platelet aggregation recovered more slowly in group 3 (hypothermia without aprotinin) than in the other groups and showed significant differences with them as late as 5 hours after operation. On the first postoperative day, all aggregation variables had returned

to or exceeded baseline values (ranging from +2% to +28% relative to baseline values).

None of the patients sustained sequelae after the study. All patients were discharged from the intensive care unit on the third postoperative day at the latest.

Comment

During CPB, contact between blood and nonphysiological surfaces affects both cellular and noncellular constituents [13, 15]. Platelets are altered during bypass in many ways. Activation of platelets by CPB leads to decreased adhesiveness, reduced membrane binding of fibrinogen, alpha granule release, and a reduced in vitro response to adenosine diphosphate and collagen [12-14, 19, 20]. The precise defects responsible for platelet dysfunction secondary to CPB are controversial. Hypothermia is reported to be one important factor by which platelet function can be significantly altered [21-24]. Lu and colleagues [25] demonstrated that lowering the incubation temperature from 37° to 22°C results in an increase in the expression of fibrinogen receptors, platelet release, and platelet aggregation.

In the present study, aggregometry was used because it is reported to be an established technique for evaluating platelet function in cardiac surgery [12, 13, 19]. Like others [26], we found a reduced platelet aggregability in all patients after CPB. Friedenbergs and associates [26] demonstrated abnormalities in aggregation with all three inducers—epinephrine, collagen, and adenosine diphosphate—in patients undergoing CPB: the second phase of platelet aggregation with epinephrine was abolished, the response to collagen was delayed and attenuated, and the response to adenosine diphosphate was attenuated with early disaggregation. In the present study, not only were alterations in platelet function most pronounced in patients who underwent hypothermic CPB without aprotinin (group 3), but also recovery of platelet function in the later postbypass period occurred more slowly compared with the other groups. Moreover, postoperative blood

Fig 1. Postoperative blood loss (in milliliters) in the four groups. CPB = cardiopulmonary bypass.

loss and need for homologous blood and blood products were highest in group 3, indicating the negative influence of hypothermia during CPB on hemostasis, including platelet function.

In several studies [7-10], aprotinin was demonstrated to be the most promising pharmacological intervention to

improve hemostasis and reduce blood loss in cardiac surgery, and routine use of aprotinin was reported to be a safe measure to make cardiac operations "drier." The properties causing the beneficial effect of aprotinin are controversial [27]. However, direct (by stabilization of platelet membrane receptors) or indirect (by its antifibri-

nolytic action) preservation of platelets was shown to be one of the major actions of this substance [28–30]. The use of aprotinin resulted in inhibition of the plasmin-related degradation of GP 1b receptor in platelets [29]. Thus, the antifibrinolytic properties of aprotinin may affect platelets in this way [31].

Some studies reported increased fibrinolytic activity during CPB with a resulting increase in fibrin degradation products. Fibrin degradation products appear to interfere with platelet function [32]. Bick [23], however, demonstrated that there is a poor correlation between levels of circulating fibrin degradation products and the degree of abnormal platelet function during CPB. Also, in a recent study by Marx and colleagues [31], aprotinin failed to cause any relevant inhibition of platelet stimulation during cardiac operations. These results are in accordance with those of the present study, in which platelet aggregation in aprotinin-treated and nontreated *normothermic* patients was without significant differences. Postoperative blood loss and the need for homologous blood were also comparable in these two groups.

However, a definitely positive effect of aprotinin was noticeable when hypothermia was used during bypass. In hypothermic patients, treatment with high-dose aprotinin resulted in significantly less reduced maximum platelet

aggregation and maximum gradient of platelet aggregation compared with the nontreated patients. Moreover, the recovery of platelet function was as quick as in the normothermic groups. This indicates that the undesirable abnormalities of platelet function during hypothermic CPB appear to be diminished when aprotinin is used. Blood loss and use of packed red cells and fresh frozen plasma were also significantly reduced when aprotinin was given in this situation.

One explanation for these results is that platelet membrane receptors, which are a prerequisite for guaranteeing intact platelet function, are particularly susceptible to alterations during hypothermic CPB. One of the assumed mechanisms by which aprotinin reduces bleeding is minimization of the loss of membrane receptor compounds (ie, GP 1b). Thus the major effect of aprotinin in this situation seems to be protection of the platelets at the molecular level [28].

The recovery of platelet function in the late postbypass period in *all* groups (including hypothermic patients without aprotinin) appears to be either due to restoration of platelet membrane receptors or due to arrival of young, hyperaggregating platelets from platelet pools in the lungs and bone marrow [23].

Fig 5. Changes in maximum (max.) platelet aggregation and maximum gradient of platelet aggregation induced by epinephrine (25 μ mol/L) compared with preoperative control. (SD = standard deviation; $\bar{x}$ = mean; other abbreviations are the same as in Figure 1.)

Interstudy comparisons of the use of aprotinin are difficult because of dissimilarities in the study conditions. The varying results are due partly to differences in type of oxygenator and pump, flow rates, suction techniques, degree of hypothermia, bypass times, and blood concentration techniques [12, 13, 23]. In some studies [9] that impressively demonstrated the beneficial effects of aprotinin, untreated control patients showed an *average* blood loss of approximately 1,200 mL with a standard deviation of approximately 600 mL after 24 hours. This indicated that some patients had a blood loss of approximately 3,000 mL postoperatively without having reoperation. The postoperative need for blood or blood derivatives was rather high (2.3 ± 2.2 units per patient) in these studies. In many of these studies, hypothermia was used, but the actual temperatures during bypass (blood, nasopharyngeal, and rectal) were not provided. Moreover, bubble oxygenators were often used although it has been reported that they predispose patients to hemostatic problems [33], and a cell saving device was used although it seems to be less effective in reducing blood loss than a hemofiltration device. In an extensive review of all recent studies dealing with aprotinin, Wildevuur [34] stated that the greater the blood activation and damage that occur, the greater the hemostatic benefits of aprotinin.

On the basis of these findings, we think that instead of the indiscriminate administration of aprotinin, it would be more logical to optimize perfusion conditions, by using a membrane oxygenator instead of a bubble oxygenator, normothermia instead of hypothermia, and hemofiltration rather than a cell saving device. Finally, the expertise of the surgeon markedly contributes to all attempts to limit blood loss in the postbypass period. When all these aspects are optimized, the role of aprotinin as a pharmacological device to improve platelet function and to reduce the use of homologous blood appears doubtful. As long as the risk/benefit ratio [35], the (weight-related?) dose, and even the mechanisms of its blood loss-reducing properties [27] are open to speculation, future controlled studies are warranted to answer these points concerning the efficacy of aprotinin in cardiac surgery.

Notice From the American Board of Thoracic Surgery

The part I (written) examination will be held at the Hilton Executive Conference Center, Dallas Fort Worth Airport, Dallas, TX, on February 13, 1994. The closing date for registration is August 1, 1993.

To be admissible for the part II (oral) examination, a candidate must have successfully completed the part I (written) examination.

A candidate applying for admission to the certifying examination must fulfill all the requirements of the board in force at the time the application is received.

Please address all communications to the American Board of Thoracic Surgery, One Rotary Center, Suite 803, Evanston, IL 60201.

Topical Use of Aprotinin in Open Heart Operations

Harun Tatar, MD, Sertaç Çiçek, MD, Ufuk Demirkılıç, MD, Ertuğrul Özal, MD, Hikmet Süer, MD, Ömer Öztürk, MD, and Hamit Işıklar, MD

Department of Cardiovascular Surgery, GATA, Gulhane School of Medicine, Etlik, Ankara, Turkey

Among various pharmacological agents used to reduce bleeding after open-heart operations, high-dose aprotinin therapy seems most promising. However, its long-term effects are still obscure; there is almost always possibility of bypass graft occlusions produced by the hypercoagulable state induced by aprotinin in coronary bypass operations. Topical application of aprotinin into the pericardial cavity could prevent the adverse effects. Fifty patients were prospectively studied to evaluate the effects of topical aprotinin. One million KIU of aprotinin was poured into the pericardial cavity before closure of

the sternotomy in group 1 (n = 25). Patients in group 2 (n = 25) served as controls. Total postoperative bleeding was significantly reduced in group 1 when compared with that of group 2 (722.7 ± 230.8 versus $1,282.6 \pm 225.7$ mL; $p < 0.01$). The use of banked donor blood products was significantly less in group 1 than in group 2 (0.33 ± 0.67 versus 1.36 ± 0.86 units; $p < 0.01$). These results show that topical use of aprotinin reduces postoperative blood loss and need for transfusion. It seems promising and warrants further studies to be done.

(*Ann Thorac Surg* 1993;55:659–61)

Bleeding after cardiopulmonary bypass (CPB) is still a major problem facing cardiac surgeons. The harmful effects of CPB on the hemostatic mechanisms is well-known. The hemorrhagic diathesis associated with CPB has a wide range including thrombocytopenia, increased fibrinolysis, decreased clotting factors, unneutralized heparin, excessive protamine, and disseminated intravascular coagulation [1–4]. The actual incidence of life-threatening hemorrhage associated with CPB is in the range of 5% to 25% [4]. The fear of transmitting infectious diseases by transfusion of homologous blood and blood products, shortages of donor blood, and financial costs have led to development of a variety of blood-saving methods. These include normovolemic hemodilution, intraoperative autotransfusion, postoperative return of shed mediastinal blood, and the use of pharmacological agents such as prostacyclin, dipyridamole, desmopressin acetate, ϵ -aminocaproic acid, and aprotinin [5–7].

Aprotinin, a known inhibitor of plasmin and kallikrein [5, 6], has been shown to reduce bleeding in several studies [7–12]. Further studies are needed to clarify its mechanisms of action and to identify the long-term results. Adverse reactions to aprotinin, a history of acute pancreatitis, severe kidney and liver dysfunction, and most important the possibility of early graft closure in coronary artery bypass operations might prevent the routine use of aprotinin in open heart operations. Drawbacks of aprotinin have led us to use aprotinin topically in the pericardial cavity. This study was designed to show the effect of topical aprotinin in reducing postoperative blood loss.

Material and Methods

This study was conducted on 50 otherwise healthy male patients scheduled for elective coronary artery bypass grafting. Patients who received platelet-active drugs within 14 days of operation or who had any kind of bleeding diathesis were excluded from the study. Informed consent was obtained from all patients. They were randomly assigned to group 1 (aprotinin group) and group 2 (control group). Aprotinin (Trasylol; Bayer AG, Leverkusen, FRG) was supplied by the hospital pharmacy in bottles containing 50 mL of saline solution without any other additives or preservatives. Each milliliter of solution contained 10,000 kallikrein inactivator units (KIU) of aprotinin. Before closure of the median sternotomy, mediastinal and thoracic drains were clamped and 100 mL of aprotinin solution (1,000,000 KIU) at room temperature was poured into the pericardial cavity. The clamps on the mediastinal and thoracic drains were released after closure of the median sternotomy, and gravity drainage was allowed. After the patient was transferred to the intensive care unit, continuous low-grade suction supplemented with periodic milking of drains was applied.

The anesthetic management and conduct of CPB were standardized. All patients were premedicated with flunitrazepam (1 mg) orally and morphine (0.1 mg/kg) intramuscularly. Anesthesia was induced with flunitrazepam (0.02 mg/kg) and fentanyl (40 μ g/kg) given over 3 minutes. Pancuronium bromide (0.15 mg/kg) was used for muscle relaxation. The extracorporeal circuit consisted of a hollow-fiber membrane oxygenator (Terumo Copiox E, Terumo Co, Tokyo, Japan). Polyvinyl chloride tubing was used throughout the circuit except for the roller pump tubing, which was silicone rubber. Patients were heparinized before CPB with 300 U/kg heparin; whenever the

Table 1. Patient Data^a

Variable	Group 1	Group 2	<i>p</i> Value
Age (y)	56.5 ± 6.8	58.7 ± 9.1	NS
CPB time (min)	90.7 ± 31.5	96.5 ± 31.7	NS
Total operative time (min)	159.8 ± 33.2	165.0 ± 32.9	NS
Average No. of distal anastomoses	3.22 ± 1.28	3.41 ± 0.96	NS
Preop hemoglobin (g/dL)	14.5 ± 0.8	14.3 ± 0.7	NS

^a Data are shown as mean ± standard deviation.

CPB = cardiopulmonary bypass; NS = not significant.

activated clotting time was shorter than 400 seconds, additional doses of heparin were given. After CPB, heparin was neutralized with protamine sulfate at a 1:1 ratio.

Mild to moderate hypothermia, cold crystalloid potassium cardioplegia (Plegisol; Abbott Laboratories, North Chicago, IL), and topical myocardial cooling with cold saline solution were employed for myocardial protection. Left internal mammary artery grafts supplemented with saphenous vein grafts were used routinely in all patients. The left pleural space was opened intentionally during left internal mammary artery harvesting.

The bleeding time, prothrombin time, activated partial thromboplastin time, and platelet counts were measured before the operation and when the patients arrived at the intensive care unit. The shed mediastinal blood was collected in a Receptaseal Thoracic autologous blood transfusion kit (Abbott Laboratories), and the amount was measured every half hour for the first day and hourly thereafter. The mediastinal and thoracic drains were removed when the total drainage was less than 100 mL over the previous 8 hours. Blood and blood components were administered only when the hematocrit value fell to less than 0.24 in the postoperative period. Shed mediastinal blood was not transfused in any patient during this study.

The number of grafts, duration of CPB, total operation time, cross-clamp time, incidence of reoperation for bleeding, amount of total chest tube drainage and total waste blood hemoglobin content were recorded for all patients. Plasma aprotinin levels were determined with the sandwich-enzyme-linked immunosorbent assay technique.

Student's *t* test was used for statistical analysis. A *p* value less than 0.05 was considered statistically significant. Data were reported as mean ± standard error of the mean. Statistical analyses were made using the Microstat (Ecosoft Inc, CA) statistical software package.

Results

There were no statistically significant differences between the two groups with regard to age, sex, duration of operation, CPB time, and average number of distal anastomoses (Table 1). There were also no significant differ-

ences between the two groups in postoperative hemodynamics, duration of intensive care, and postoperative hospital stay (data not shown).

Chest tube drainage in the first 24 hours was 420 ± 150 mL in the aprotinin group and 650 ± 225 mL in the control group (*p* < 0.05). Total postoperative chest tube drainage was 722.7 ± 230.8 mL (range, 300 to 1,100 mL) in group 1 (aprotinin) and 1,282.6 ± 225.7 mL (range, 750 to 1,700 mL) in group 2 (control) (*p* < 0.01) (Fig 1). The hemoglobin loss in the total chest tube drainage was 16 g in the aprotinin group and 49 g in the control group (*p* < 0.01). The color of drainage was pale. The drainage after the first 24 hours was mostly due to loss of tissue fluid. The use of banked donor blood products intraoperatively was not significantly different between two groups. However, the aprotinin group needed significantly less banked donor blood in the postoperative period (0.33 ± 0.67 versus 1.36 ± 0.86 units; *p* < 0.01). The percentages of patients receiving banked donor blood were 26.6% in the aprotinin group and 84.6% in the control group (*p* < 0.01).

Aprotinin levels were determined in 8 patients in the aprotinin group at the first hour after unclamping of the chest tubes. Aprotinin was not detected in any of the patients' blood.

Preoperative hemoglobin levels were not significantly different between the two groups. On postoperative day 1, the hemoglobin level was 9.1 ± 0.7 g/dL in the aprotinin group and 8.6 ± 0.9 g/dL in the control group (not significant).

There were no statistically significant differences between the two groups with regard to bleeding time, prothrombin time, activated partial thromboplastin time, activated clotting time, and platelet counts preoperatively and postoperatively.

None of the patients were reoperated on for bleeding.

Fig 1. Postoperative blood loss.

All patients were discharged from the hospital in good condition.

Comment

Various clinical investigations have shown that high-dose aprotinin reduces postoperative blood loss significantly [7-12]. The mechanism of this effect remains unclear. Aprotinin exerts an inhibiting effect on proteolytic enzymes, forming an aprotinin-proteinase complex. It inhibits trypsin, plasmin, and tissue and plasma kallikreins [13]. Plasmin and kallikrein are generated by CPB; kallikrein activates Hageman's factor and activates plasminogen to form plasmin [14]. In low concentrations aprotinin inhibits plasmin completely, thereby inhibiting fibrinolysis, although at very high concentrations, inhibition of kallikrein reduces blood coagulability [15]. Royston and associates [8] and van Oeveren and co-workers [6] suggested that aprotinin exerts its effect by protecting the function of platelets. Further studies must be done to clarify aprotinin's mechanism of action.

Topical application of aprotinin into the pericardial cavity might prevent the adverse effects of aprotinin. The results of this study showed that topical use of aprotinin significantly reduced postoperative blood loss and the need for banked donor blood transfusions. The reduction in postoperative blood loss in our study was comparable with that in other studies in which the aprotinin was applied systematically [7, 11, 12]. This method of topical application of aprotinin will be especially useful in patients in whom the internal mammary arteries are used because the wound area, and thus bleeding, is more profound in these patients.

One hundred milliliters of aprotinin solution applied topically reduced the need for banked donor blood. In 18 of 25 patients no donor blood was used postoperatively. The reduction in use of banked donor blood could limit the problems associated with transfusion.

Dietrich and colleagues [11] reported that due to its effects on hemostasis, there is almost always the possibility of early graft closure with the use of aprotinin; further studies are needed to clarify this issue. Topical use of aprotinin will completely abolish this problem.

The total amount of aprotinin may be reduced by this method, which is important for the cost-benefit ratio.

Aprotinin could not be detected in any of the 8 patients' blood. This shows that the drug remains restricted to the pericardial space and the effect is completely due to topical action.

In conclusion, further studies must be done to explain the mechanism of topical aprotinin action. The use of aprotinin topically resulted in a significant reduction in postoperative blood loss and might be an alternative to its systemic use.

We greatly appreciate the help of Dr W. Wingender from Bayer AG, Institute of Clinical Pharmacology, Wuppertal-Elberfeld, Federal Republic of Germany, for the blood aprotinin determinations.

Effects of Aprotinin on Anticoagulant Monitoring: Implications in Cardiovascular Surgery

David M. Najman, MD, Jeanine M. Walenga, PhD, Jawed Fareed, PhD, and Roque Pifarré, MD

Departments of Pathology and Thoracic and Cardiovascular Surgery, Loyola University Medical Center, Maywood, Illinois

This study was designed to evaluate anticoagulant monitoring of heparin and platelet function in the presence of aprotinin. Aprotinin added to heparinized whole blood at concentrations equal to (30 $\mu\text{g/mL}$), twice, and four times that used in cardiopulmonary bypass operations synergistically elevated the activated clotting time (ACT) (536 ± 73 , 651 ± 86 , and 787 ± 71 seconds, respectively) over the value with heparin alone (384 ± 66 seconds) ($p < 0.001$). In addition, the ACT of heparin-protamine mixtures supplemented with protamine showed that the heparin was not completely neutralized (131 ± 12 versus 98 ± 7 seconds). Specific tests revealed that the effect on ACT caused by aprotinin is not equal to the anticoagulant effect of heparin. Thus there is a risk of underheparinization if the ACT is used as a monitor when aprotinin is present. Furthermore, protamine doses relative to

the heparin concentration, and not relative to the ACT, should be used to reverse heparin. In studying the effects of aprotinin on platelet function, there was a significant inhibition of aggregation when normal platelets were supplemented with aprotinin, but not for platelets of postoperative patients. This suggests that aprotinin may interact more favorably with nonactivated platelet surfaces, reducing or inhibiting the expression of receptors. Thus it is necessary to treat a patient with aprotinin before beginning cardiopulmonary bypass. Based on these data, the effect of aprotinin on the hemostatic system and its drug interactions must be considered to optimize safety and efficacy during cardiopulmonary bypass operations.

(*Ann Thorac Surg* 1993;55:662-6)

Aprotinin has been used in many clinical situations to improve hemostasis in patients undergoing cardiopulmonary bypass (CPB) operations, with no reported side effects [1-6]. It inhibits kallikrein, plasmin, trypsin, chymotrypsin, and other proteases [7, 8], and it also affects receptors on platelet membranes [3, 5, 9, 10]. The decrease in blood loss in CPB operations with the use of aprotinin has been attributed to preservation of the adhesive capacity of platelets [2]; however, other mechanisms may also be affecting hemostasis.

We were interested in the effect of aprotinin on heparin dosage monitoring with the whole blood clotting time assay (ACT) during cardiac operations [11], particularly in view of recent clinical data showing increased thrombotic complications after cardiac operations with aprotinin [12]. Platelet-protamine interactions were also studied to further address the mechanism of action. Because aprotinin has not been released for clinical use in the United States, it was necessary to perform in vitro experiments. The combined heparin-protamine effect on the ACT in hemodiluted blood taken during cardiac operations from patients on CPB pump was also evaluated to anticipate possible perioperative procedural modifications.

Material and Methods

Study Design

This study was divided into three phases as follows.

PHASE 1. In vitro clotting times were performed using a stock concentration of 10.0 mg/mL aprotinin, which was added to pooled normal human plasma in a final plasma concentration range of 1.0 $\mu\text{g/mL}$ to 1.0 mg/mL ($n = 5$). Controls were plasma supplemented with saline solution. Prothrombin time (Dade, Miami, FL), activated partial thromboplastin time (APTT; Organon Teknika, Durham, NC), and Heptest, a clot-based heparin-sensitive APTT-like assay (Haemachem, St. Louis, MO) were performed. Aprotinin from Sanofi (Paris, France; lot VB101-RB22111) and Pentapharm (Basle, Switzerland; lot 5388/074) were compared.

PHASE 2. A second-phase (four parts) in vitro study used fresh whole blood collected from normal human subjects ($n = 10$). At each blood draw the first 3 mL was discarded and the remaining blood was aliquoted to syringes containing the solutions shown in Table 1.

Activated whole blood clotting time was measured immediately using the Hemochron 800 (International Technidyne, Edison, NJ) instrument. The remaining blood mixtures were placed in sodium citrate (9 mL blood to 1 mL citrate) and centrifuged for platelet-rich plasma and platelet-poor plasma. Platelet aggregation studies were then performed using a Bio/Data PAP-4 (Hatboro,

Accepted for publication June 29, 1992.

PA) aggregometer. Final concentrations of arachidonic acid (33 $\mu\text{g/mL}$), adenosine diphosphate (2.5×10^{-6} mol/L), collagen (0.8 $\mu\text{g/mL}$), and epinephrine (10 $\mu\text{g/mL}$) were used to stimulate platelet aggregation. Hematocrits were measured in the hemodilution-simulated samples (part D).

PHASE 3. In a third phase of the study, blood obtained from patients undergoing CPB operations was evaluated ($n = 15$). Blood was drawn after anesthesia induction, 10 minutes after the initial heparin bolus (2.5 mg/kg), and 10 minutes after the entire protamine dose was given at the end of the operation. The initial 3 mL of blood was discarded, and the remaining 9 mL of blood was added to syringes containing either 1.0 mL of aprotinin (0.3 mg/mL) or 1.0 mL of saline solution. The ACT was measured immediately, and the remaining blood was used for aggregation studies as described above.

Laboratory results and patient information were obtained from the patients' medical records. All results are given as a mean $\pm$ one standard deviation.

Results

There were no significant changes in the prothrombin time, Heptest, or thrombin time at any concentration of aprotinin added in vitro to pooled human plasma. The APTT was elevated in a dose-dependent manner with aprotinin. The increase in APTT was 3 to 4 times baseline at a final plasma concentration of 1.0 mg/mL, and 1.5 to 2 times baseline at therapeutic concentrations (30 to 60 $\mu\text{g/mL}$ final plasma concentrations). The Sanofi and Pentapharm aprotinins showed comparable effects with no significant differences between the two drugs.

In the whole blood studies, there was a slight prolongation of the ACT to 126 ± 15 and 135 ± 19 seconds by

aprotinin added at a final blood concentration of 30 and 60 $\mu\text{g/mL}$, respectively ($p < 0.05$). The normal ACT for nontreated whole blood was 98 ± 7 seconds. There was a dose-dependent effect of aprotinin on the ACT. There were no significant differences between the Sanofi and Pentapharm aprotinins at the concentrations studied.

Heparin evaluated at a concentration identical to that used in CPB operations (2.5 U/mL blood) resulted in an ACT at the level desired during CPB operations, eg, 400 seconds. Addition of aprotinin (60 $\mu\text{g/mL}$) caused a synergistic anticoagulant response with heparin (ACT, 651 ± 87 seconds) elevating the ACT response above that caused by aprotinin (142 ± 9 seconds) or heparin (385 ± 66 seconds) alone or by a simple addition effect of the two agents (Fig 1). This effect was dose-dependent.

In a similar experimental setting, the effect of protamine was studied. The anticoagulant effect of heparin was completely reversed with protamine used at the ratio of 1 mg protamine to 100 U heparin, but protamine did not neutralize the aprotinin effect (Fig 2). With protamine added, the ACT of the aprotinin-heparin group (see Fig 2, bar 4) returned to the level of the nonheparinized but aprotinin-added group (see Fig 2, bar 1). A baseline level of 98 ± 7 seconds was not achieved; the aprotinin anticoagulant effect remained.

In an attempt to establish conditions similar to those in a patient undergoing CPB, 33% hemodiluted (buffer plus saline solution) blood was evaluated with aprotinin supplementation. The decrease in hematocrit was similar to that seen in CPB patients during operation (0.40 ± 0.04 decreased to 0.24 ± 0.05). The ACT was slightly but not significantly elevated in the hemodiluted blood in comparison with the normal blood (149.1 ± 13.9 versus 133.9 ± 10.9 seconds) with aprotinin supplementation (30 $\mu\text{g/mL}$).

Fig 1. Effect of aprotinin and heparin on the activated clotting time in normal volunteers. Group 1 = aprotinin (60 µg/mL); group 2 = heparin (2.5 U/mL); group 3 = aprotinin (60 µg/mL) + heparin (2.5 U/mL); and group 4 = aprotinin (125 µg/mL) + heparin (2.5 U/mL). Results are given as a mean $\pm$ 1 standard deviation (n = 10). Aprotinin added to heparin produces a synergistic response on the activated clotting time.

The effect of aprotinin in blood obtained from patients while on CPB during operation was similar to that reported above for the hemodiluted bloods of normal donors. There was once again a synergistic anticoagulant effect of aprotinin with heparin, and there was a return to the aprotinin ACT value after addition of protamine (Fig 3).

For the supplemented blood collected from normal volunteers, the maximum platelet aggregation response and the slope of aggregation for all agonists tested in the aprotinin-supplemented platelet-rich plasma was signifi-

Fig 2. Effect of aprotinin, heparin, and protamine on the activated clotting time in normal volunteers. Group 1 = aprotinin (30 µg/mL); group 2 = heparin (2.5 U/mL); group 3 = aprotinin (30 µg/mL) + heparin (2.5 U/mL); and group 4 = aprotinin (30 µg/mL) + heparin (2.5 U/mL) + protamine (25 µg/mL). Results are given as a mean $\pm$ 1 standard deviation (n = 10). Protamine sulfate reverses the anticoagulant effect of heparin but not of aprotinin.

Fig 3. Effect of aprotinin supplementation on the activated clotting time during cardiopulmonary bypass operation. Time 0 = anesthesia; time 1 = 10 minutes after pump; and time 2 = after protamine infusion. Results are given as a mean $\pm$ 1 standard deviation (n = 15). Aprotinin synergistically elevated the activated clotting time response in the presence of heparin; protamine sulfate did not reverse the anticoagulant response of aprotinin in patients.

cantly decreased from non-aprotinin-supplemented samples ($p = 0.001$), although individual variations were observed (Fig 4). There were no significant differences between the various aprotinin concentrations tested. The decrease in slope of aggregation was related to an inhibition of the onset of the second wave of aggregation. The most remarkable finding was the disaggregation response seen in the aprotinin-supplemented samples when adenosine diphosphate was used as an agonist (Fig 5). This was not observed with the other agonists (collagen, epinephrine, arachidonic acid).

Fig 4. Platelet aggregation in the presence of aprotinin. Platelets of normal volunteers were activated with adenosine diphosphate. Group 1 = heparin (2.5 U/mL); group 2 = aprotinin (60 µg/mL); group 3 = heparin (2.5 U/mL) + aprotinin (60 µg/mL); and group 4 = heparin (2.5 U/mL) + aprotinin (125 µg/mL). Results are given as a mean $\pm$ 1 standard deviation (n = 10). Platelet aggregation induced by collagen, epinephrine, and arachidonic acid showed similar results.

Fig 5. Typical platelet aggregation response of normal volunteer platelets supplemented with aprotinin, heparin, protamine sulfate, or a combination. Adenosine diphosphate was used as an aggregating agent. Line 1 = heparin (2.5 U/mL); line 2 = aprotinin (30 µg/mL); line 3 = heparin (2.5 U/mL) + aprotinin (30 µg/mL); line 4 = heparin (2.5 U/mL) + aprotinin (30 µg/mL) + protamine (25 µg/mL). Note no effect by heparin alone on platelet aggregation (group 1) but platelet disaggregation (reversibility) in groups 2 and 4.

The presence of heparin eliminated the inhibitory effect of aprotinin. In the presence of heparin plus protamine, the inhibition of platelet aggregation by aprotinin could be observed (Fig 5).

In CPB patients the platelet aggregation decreased, as expected, as the operation progressed; we attributed this to both dilutional and traumatic effects to the platelets by the CPB pump. Contrary to what was found in normal human donors, there was no significant difference in aggregation response in the ex vivo aprotinin-supplemented and nonaprotinin groups for any intraoperative or postoperative sample. Moreover, there was a trend toward an increase in the aggregation response when aprotinin was added ex vivo to patient blood taken after protamine was given.

Comment

This study was mainly designed to examine aprotinin's effects on anticoagulant monitoring, namely the ACT, which is used at many institutions to monitor the anticoagulant level in CPB patients intraoperatively. An attempt was also made to evaluate the effects of aprotinin on platelet function due to the reported clinical effects observed [5, 10].

Our in vitro studies showed that the APTT was elevated in a dose-dependent fashion most likely via the inhibitory effects of aprotinin on kallikrein and thus the contact/intrinsic system. There were no effects on the other aspects of the coagulation profile (prothrombin time, thrombin time, Hep-test), demonstrating that the anticoagulant effect of aprotinin observed by the ACT is not heparinlike. Although there was an increase in the ACT

with aprotinin supplementation, because this anticoagulant effect cannot be attributed to a heparinlike quality, it is not appropriate to assume that the aprotinin synergistic enhancement of the ACT would allow for reduced heparinization [12].

For adequate anticoagulation with heparin, the goal during CPB operation is to maintain an ACT of 400 seconds [13]. This dose effect has worked well in the past. However, with new drug treatments the relationship between the heparin dose and the ACT response can be modified. For a given ACT response (eg, 400 seconds) in CPB patients who are given aprotinin, lower doses of heparin would actually be used than in patients not given aprotinin because aprotinin also affects the ACT. Because the aprotinin effect is not heparinlike, and it has not been shown that patients can be adequately anticoagulated during CPB with lower heparin doses, adverse side effects could be observed. This may be one explanation for the increased incidence of myocardial infarction observed in a recent clinical trial of aprotinin [12]. Controlled trials must be performed to examine this, looking in particular for renal, cerebral, and cardiac insufficiency.

Protamine reversal of heparin, in the presence of aprotinin, neutralized the synergistic anticoagulant effect of heparin but not the anticoagulant effect of aprotinin. Therefore, in CPB patients given aprotinin, protamine doses relative to the heparin concentration in the body, and not relative to the ACT, should be used to reverse the effect of heparin at the end of a cardiac operation. Furthermore, when used with hemodiluted blood, there was an increase in the ACT over nonhemodiluted aprotinin-supplemented blood, but this effect was most probably

due to the hemodilution and not a stronger aprotinin effect.

The second phase of this study using normal volunteers showed that there was an inhibition of platelet aggregation induced by epinephrine, adenosine diphosphate, arachidonic acid, and collagen in vitro in both the aprotinin- and aprotinin/heparin/protamine-supplemented groups. However, with only aprotinin and heparin, platelet aggregation was unaltered. In the ex vivo CPB patient study, contrary results were obtained. The inhibitory effect of aprotinin supplementation was not observed in blood obtained from CPB patients immediately after coming off pump. Aprotinin appears to interact more favorably with the glycoprotein receptors of nonactivated platelets than of activated platelets, delaying aggregation. This could theoretically preserve platelet integrity by decreasing the activation response of the platelets caused by the traumatic effect of the CPB pump and heparin exposure. Thus aprotinin would only be effective when patients are pretreated before exposure of the platelets to the CPB pump or other mechanisms of platelet activation.

Preservation of platelet function is thought to be important to reduce postoperative blood loss. However, further studies, including thromboxane and prostaglandin measurements, need to be performed on patients receiving aprotinin intraoperatively to identify the extent of platelet activation in individual patients. It has been shown that hyperactive platelets contribute to thrombotic risk [14]. Whether aprotinin treatment produces a relative hyperactivity of platelet function in all or some of the CPB surgical patients should be determined and related to thrombotic clinical events associated with aprotinin use.

Furthermore, aprotinin inhibits the fibrinolytic system. At this early stage of using aprotinin clinically, it is important to evaluate the individual patient's preoperative fibrinolytic status. It is known that patients have variable levels of the fibrinolytic parameters [15], and that patients with cardiovascular disease have abnormal activity levels [16]. As there are individual responses to heparinization, it is likely that there will be individual responses to aprotinin. Thus, whether the best clinical approach will be an unadjusted dose or a patient-tailored dose with a contraindication for use in specific patients remains to be determined.

The fact that aprotinin affects the ACT response, which is used to determine heparin dosing, the fibrinolytic system, and platelet aggregation suggests the need for conducting more comprehensive experimental and clinical studies on aprotinin to determine optimal dosing regimens.

With The
MONOLYTH,
Superior
Performance
Is A Matter
Of Course.

THE CHEVRON-GROOVED, CLOSELY PACKED, PLEATED SHEET OF THE MONOLYTH'S HEAT EXCHANGER ENHANCES BLOOD MIXING WITHOUT HEMOLYTIC TURBULENCE. THIS THIN, STAINLESS STEEL, EPOXY-COATED SHEET TRANSFERS HEAT TO THE THIN BLOOD FILM WITH REMARKABLE EFFICIENCY. AND A UNIQUE FAIL-SAFE DESIGN PREVENTS THE POSSIBILITY OF A SEAL-RELATED WATER LEAK FROM ENTERING THE SYSTEM.

THE MONOLYTH'S EXCEPTIONAL PERFORMANCE IS MATCHED BY EXCEPTIONAL SAFETY. AS BLOOD FLOWS DOWNWARD, NATURAL BUOYANCY HOLDS AIR IN THE BUBBLE TRAP AT THE TOP OF THE UNIT, WHERE IT'S FORCED OUT THE UNIQUE MONOLYTH PURGE PORT. THE RESULT? MONOLYTH RATED BEST IN AIR REMOVAL.* AN ADDED LEVEL OF CONFIDENCE IN EVERY PROCEDURE.

THE MONOLYTH ACHIEVES HIGH OXYGENATION PERFORMANCE AND LOW PRIMING VOLUME THROUGH A REVOLUTIONARY MAT FIBER DESIGN WITH UNIFORM, EQUALLY SPACED FIBERS, PLUS A SHORT, NORMAL-CROSS PERPENDICULAR FLOW PATH. IN FACT, THE MONOLYTH PROVIDED THE LOWEST PRESSURE DROP OF ANY OXYGENATOR TESTED.*

THE CLEAR HOUSING OF THE MONOLYTH GIVES PERFUSIONISTS EXACTLY WHAT THEY WANT — COMPLETE VISIBILITY AND CONTROL OVER EVERY ASPECT OF EVERY CASE.

A UNIQUE ARTERIAL STOPCOCK FUNCTIONS AS A RECIRCULATION PORT, SHUNTING BLOOD BACK TO THE VENOUS RESERVOIR FOR EASIER PRIMING, AIR REMOVAL, RE-OXYGENATION OR RECIRCULATION. EQUALLY IMPORTANT, IT INCORPORATES A LUER-LOCK FACILITY TO FACILITATE BLOOD CARDIOPLEGIA, HEMOCONCENTRATION AND POST-PROCEDURE BLOOD RECOVERY.

Introducing The **MONOLYTH** Uncompromising Design From Top To Bottom.

With most oxygenators, you have to give up something to get something. Compromise is a typical part of the performance equation.

The new Monolyth, however, is not a typical oxygenator. Because its innovative mat fiber design with uniform, equally spaced fibers promotes exceptional gas transfer performance and a remarkably low pressure drop.

The Monolyth also incorporates a unique flow path that runs perpendicular to the bundle, plus a bubble trap for

greater efficiency and safety. Along with an uncompromising heat exchanger. And a compact, low-prime design that helps take performance to an entirely new level.

So what you get is an oxygenator that reflects our constant commitment to technology that is not only state of the art. But technology that takes the art of perfusion to an entirely new state.

For more information, contact your Sorin representative today. And start experiencing the ultimate performance course.

Founded almost two decades ago, Sorin Biomedica S.p.A. has become one of the world's leading manufacturers of innovative cardiovascular technology with a special emphasis on oxygenators, heart valves, pacemakers, vascular grafts, immunodiagnostics and biocompatible materials. The company's entrance into the U.S. market through the acquisition of Shiley, Inc., and the resultant creation of Sorin Biomedical, Inc., in early 1992 gives clinicians across the country access to a much wider array of pioneering new products than ever before.

Effects of External Stenting on Wall Thickening in Arteriovenous Bypass Grafts

Adonis G. Violaris, MRCP, Andrew C. Newby, PhD, and Gianni D. Angelini, FRCS

Cardiac Surgery Department, University of Sheffield, Sheffield, and Cardiology Department, University of Wales College of Medicine, Cardiff, United Kingdom

Late occlusion of the saphenous vein graft appears to result in part from wall thickening as an adaptation to increased mean wall stress. Using an established pig model of arteriovenous bypass grafting, the effect of reducing wall stress with an external porous polytetrafluoroethylene stent was investigated. Segments of autologous saphenous vein were implanted by end-to-end anastomoses into both carotid arteries, with one graft supported by a stent 4 mm in diameter. Increases in graft wall dimensions were quantified 4 weeks later by computer-aided planimetry of transverse histological sections. The contribution of hyperplasia (i.e., cell proliferation) to the changes observed was further clarified by measurements of DNA concentration. All grafts showed an increase in external size, but this was restricted by stenting. All grafts also showed an increase in cross-

sectional area of the tunica media and tunica intima that was only partly accounted for by an increase in DNA concentration, which indicated that both hyperplasia and hypertrophy had occurred. Stented grafts showed less enlargement of the media but greater enlargement of the intima. Overall wall size was therefore similar in stented and unstented grafts. Stented grafts showed less increase in DNA concentration than unstented grafts. In stented grafts, the residual luminal cross-sectional area was significantly less than in unstented grafts. The data show that external stenting reduces medial enlargement and hyperplasia but increases encroachment of the intima into the lumen. Because final luminal size is thought to be of paramount importance in maintaining long-term patency, external stenting is unlikely to be of benefit.

(*Ann Thorac Surg* 1993;55:667-71)

Autologous saphenous vein continues to be one of the most widely used conduits for revascularization of coronary and peripheral arteries despite its disappointing long-term patency rate [1-3]. Late occlusion appears to be the result of both the intimal thickening caused by migration and proliferation of smooth muscle cells and the appearance of mature lipid-laden atherosclerotic plaques [3-5]. Both these processes probably represent adaptive changes by the vein to its insertion into the arterial system [3-5]. Factors potentially responsible for these changes may include the increased mean wall tension and the increased mean shear stress. If so, the use of an external support to limit the effect of wall tension might reduce the degree of wall thickening. To test this hypothesis, we used a previously described pig model of arteriovenous bypass grafting [6] to quantify the effects of a rigid external polytetrafluoroethylene support on the changes in intimal and medial size of the vein graft and in cell numbers reflected by DNA concentration.

Material and Methods

Surgical Procedures

Studies were performed using 15 white race pigs initially weighing 20 to 25 kg. Premedication, induction and maintenance of anesthesia, and autologous saphenous

vein to carotid artery bypass grafting were performed as detailed previously [6]. Briefly, a longitudinal incision was made on the outer aspect of the hind leg to expose approximately 12 cm of the long saphenous vein. The vein was dissected free from surrounding tissue using a "no-touch" technique [7], and all side branches were secured with a 6-0 Prolene ligature. Then the vein was removed, gently irrigated with a heparinized isosmotic sodium chloride solution (0.9 g/L), and stored in the same solution at room temperature for 20 to 40 minutes until needed.

The common carotid artery was isolated through a longitudinal neck incision, and a 3- to 4-cm segment, isolated between vascular clamps, was excised. Both cut ends were beveled to approximately 45 degrees. A segment of reversed saphenous vein was similarly beveled and then anastomosed end-to-end to the carotid artery using a continuous 7-0 Prolene suture (Ethicon, Somerville, NJ). On the opposite side, after the proximal anastomosis was completed, the vein was passed through a polytetrafluoroethylene tube (Gore-Tex, W. L. Gore & Associates Inc, Elkton, MD) 4 mm in diameter and slightly longer than the graft, after which the distal anastomosis was performed. A single 6-0 Prolene suture was used to secure the polytetrafluoroethylene graft to the adventitial tissue of the two divided ends of the carotid artery. The neck and leg wounds were closed in layers, and the animals were allowed to recover.

After 4 weeks, the animals were anesthetized as before, the neck was opened, and the graft was identified. The carotid artery was transected distal to the graft, and the

absence of blood flow was taken to indicate graft occlusion. Only patent grafts were used for analysis because graft occlusion was associated with extensive fibrotic changes that obscured the vein structure.

Microscopic Methods

The graft was removed and divided in two, and the larger segment was cannulated at one end with a syringe attached to a mercury manometer [8]. The other end of the graft also was cannulated and the cannula, was clamped. Fixative, consisting of a solution of 10% formalin in 0.1 mol/L sodium phosphate buffer, pH 7.3, was pumped into the lumen of the vessel for 5 to 10 minutes to achieve a pressure of approximately 100 mm Hg. The smaller segment was frozen in liquid nitrogen for estimation of DNA concentration. A segment of long saphenous vein from the other hind leg, ie, ungrafted vein, was obtained at the time of graft removal and was treated similarly.

Fixed grafts and ungrafted segments of vein were further fixed, dehydrated, cleared, and embedded in paraffin wax with their axis perpendicular to the cutting plane. Sections were cut at four levels approximately 0.75 mm apart, mounted on glass slides, stained with Miller's elastic stain, and counterstained with van Gieson's stain. Luminal, intimal, and medial cross-sectional areas were measured for three sections at each level by computer-aided planimetry using a Nikon microscope with a camera lucida, Hewlett-Packard computer (HP 85; Corvallis, OR), a digitizing tablet, and Graphic Information System quantitation program V3.0.

The area enclosed by the endothelium defined the lumen. The area between the endothelium and the internal elastic lamina defined the intima. The area between the internal and external elastic laminae defined the media. Luminal encroachment was defined as the percentage of the area enclosed by the internal elastic lamina occupied by the intima.

Mean values were then calculated for all sections from the same graft. Average intimal thickness was calculated from the cross-sectional area data using the following formulas and assuming that the sections consisted of circular profiles, which was a valid assumption because the tissues were fixed at normal perfusion pressure:

- (1) Luminal radius = $\sqrt{\text{luminal area}/\pi}$
- (2) Intimal thickness
 $= \sqrt{(\text{intimal} + \text{luminal area})/\pi} - \text{luminal radius}$
- (3) Medial thickness
 $= \sqrt{(\text{medial} + \text{intimal} + \text{luminal area})/\pi}$
 $- \text{luminal radius} - \text{intimal thickness}$

DNA Concentration

Frozen vessels were thawed, the adventitia was removed, and the remaining tissue was weighed and then homogenized at 4°C using a motor-driven Teflon glass homogenizer with 100 volumes of 0.3 mol/L perchloric acid until a

smooth suspension was created. The DNA concentrations were then measured as detailed previously and were expressed as micrograms per milligram of wet weight [6]. The total DNA concentration ($\mu\text{g}/\text{mm}$ graft length) was calculated as the product of DNA ($\mu\text{g}/\text{mg}$ wet weight) multiplied by wall area (mm^2), the assumption being that the tissue density was $1 \text{ mg}/\text{mm}^3$.

Echocardiographic Doppler Sonography

A Sonicaid Vasoflo III continuous-wave Duplex ultrasound system (Oxford Sonicaid, Chichester, West Sussex, England) was used to produce simultaneously a high-resolution image and the flow pattern within the grafts 10 to 20 minutes after completion of the surgical procedure, as previously described [6]. The diameters of the carotid artery, the in situ saphenous vein, and the grafts were measured at five points along their length, and the mean diameter was calculated.

Statistical Analysis

Values are shown as the mean $\pm$ the standard error of the mean with the number of observations in parentheses. Unless otherwise stated, significance between groups was established with Student's *t* test using unpaired values.

Results

All operations were performed by the same surgeon (G.D.A.). One pig failed to survive until the grafts were recovered and hence was excluded from the analyses. Unstented grafts had a patency rate of 93% ($n = 14$) and stented grafts, 79% ($n = 14$) ($p =$ not significant).

Diameter Measurements and Flow Pattern

Ultrasound measurements were made to determine the effect of stenting on the initial diameter of the vein grafts. The mean luminal diameter of the proximal and distal carotid artery at the level of grafting was $3.1 \pm 0.2 \text{ mm}$ and $3.0 \pm 0.1 \text{ mm}$, respectively ($n = 5$). Ungrafted in situ saphenous vein had a mean luminal diameter of $2.2 \pm 0.3 \text{ mm}$ ($n = 5$). Unstented grafts had a mean diameter of $3.6 \pm 0.2 \text{ mm}$ ($n = 4$) and stented grafts, $3.7 \pm 0.3 \text{ mm}$ ($n = 4$).

Ultrasound measurements were also used to determine whether stenting affected flow patterns in the grafts. Velocity at peak systole and diastolic flow were comparable in the proximal carotid artery and in both unstented and stented grafts, implying similar flow rates (Fig 1). Flow inhomogeneity (related to turbulence) quantified by Doppler spectral broadening at peak systole was similar in the middle point of both unstented and stented grafts ($54.1\% \pm 0.5\%$ and $53.8\% \pm 0.2\%$, respectively; $n = 4$).

Changes in Luminal, Medial, and Intimal Size and DNA Concentration

In ungrafted vein, the intima consisted of a confluent monolayer of endothelium. The media, which was composed of an average of ten smooth muscle cell layers, was surrounded by well-defined internal and external elastic laminae (Fig 2A).

Fig 1. Sonograms illustrating spectral flow pattern from (A) un-stented and (B) stented grafts.

In unstented and stented grafts recovered after 4 weeks, the internal elastic lamina remained unchanged, whereas the external elastic lamina became more separated (Figs 2B, 2C). A new intimal layer with both axially

Table 1. Changes in Medial, Intimal, and Luminal Areas^a

Variable	Vein (n = 24)	Unstented Graft (n = 13)	Stented graft (n = 11)
Medial area (mm ²)	1.1 ± 0.2	5.09 ± 0.63 ^b	2.25 ± 0.33 ^{b,c}
Intimal area (mm ²)	0	2.49 ± 0.45 ^b	3.98 ± 0.64 ^b
Total wall area (mm ²)	1.1 ± 0.2	7.59 ± 0.85 ^b	6.23 ± 0.20 ^b
Luminal area (mm ²)	2.3 ± 0.3	11.18 ± 1.33 ^b	1.87 ± 0.3 ^c
Luminal encroachment (%)	0	14.4 ± 2.7 ^b	55.3 ± 5.2 ^{b,c}

^a Data are shown as the mean ± the standard error of the mean; the number of observations is in parentheses. ^b Significance: $p < 0.01$ versus vein. ^c Significance: $p < 0.001$ versus unstented graft.

and circumferentially oriented smooth muscle cells was clearly present in both unstented and stented grafts (see Figs 2B, 2C).

Medial and intimal cross-sectional areas were increased by grafting. Medial cross-sectional areas increased significantly more in unstented grafts (4.6-fold) compared with stented grafts (twofold) (Table 1). In contrast, the final intimal cross-sectional area was only about half as great in unstented as in stented grafts, although the difference did not reach significance ($p = 0.1$). As a result of these inverse changes, there was no significant difference in total wall area (intimal + medial cross-sectional areas) between unstented and stented grafts. Luminal areas increased approximately fivefold in unstented grafts compared with veins but remained virtually unchanged in stented grafts (see Table 1). As a result, luminal encroachment was significantly less in unstented than stented grafts (see Table 1).

The DNA concentration per milligram of wet weight was lower in all grafts than in ungrafted vein (Table 2), as demonstrated previously [9]. This indicated that the density of viable cells had declined. The DNA concentration per milligram of wet weight was significantly greater in unstented than stented grafts (see Table 2), which indicated that the final density of viable cells was greater in unstented grafts. The calculated DNA concentration per

Fig 2. Transverse sections of (A) un-grafted vein, (B) unstented graft, and (C) stented graft. (Miller's elastin stain and van Gieson's stain as counterstain; $\times 75$ before 24% reduction.) (A = adventitial tissue; EEL = external elastic lamina; IEL = internal elastic lamina; M = media; PTFE = polytetrafluoroethylene.)

millimeter of length was significantly increased by grafting (see Table 2), which demonstrated that grafting caused an overall increase in vessel wall cell numbers. The DNA concentration per millimeter of length was significantly greater in unstented than stented grafts (see Table 2) as a result of the increased cell density.

The results of the planimetry measurements were also used to calculate mean external radii and medial and intimal thicknesses. Consistent with the increase in graft size, unstented grafts showed a 2.4-fold increase in external radius (Table 3). This was much reduced in stented grafts (1.6-fold). Wall thickness (intimal + medial thicknesses) was increased 4.1-fold in unstented grafts and significantly more, 6.1-fold, in stented grafts (see Table 3). The difference between unstented and stented grafts was due to greater intimal thickening partly compensated by less medial thickening in the stented grafts (see Table 3). As a net result, luminal radius was significantly less in stented than unstented grafts (see Table 3).

Comment

Late saphenous vein graft failure remains a major problem in coronary and peripheral artery revascularization with up to 50% of vein grafts occluded by 10 years postoperatively [2, 3, 10]. Previous studies have demonstrated that short-term graft patency may be improved by antiplatelet agents [3] or by optimal techniques of harvesting [6]. Late graft attrition, however, is influenced only marginally by antiplatelet agents or surgical technique [3, 9, 10] and thus probably represents an intrinsic adaptation of the vein to its insertion in the arterial circulation. The higher pressure and flow velocities in the arterial circulation result in increases in both mean wall tension and mean shear stress. Either or both of these factors may cause smooth muscle cell migration into the intima and subsequent proliferation [4, 11].

Surrounding the graft by a rigid external support has the theoretical advantage that wall tension will eventually be reduced or even eliminated. By limiting graft expansion, however, mean shear stress will be greater than in unstented grafts. The axial pressure pulse will be unaltered. The net effects of these differences are difficult to predict, and therefore the effect of stenting on the changes in wall dimensions was investigated empirically.

Table 2. Changes in DNA Concentrations^a

Variable	Vein (n = 24)	Unstented Graft (n = 13)	Stented Graft (n = 11)
Measured DNA concentration ($\mu\text{g}/\text{mg}$ wet wt)	2.7 ± 0.2	0.986 ± 0.15^b	$0.546 \pm 0.09^{b,c}$
Calculated DNA concentration ($\mu\text{g}/\text{mm}$ length)	1.97 ± 0.3	7.45 ± 1.41^b	$3.87 \pm 0.70^{b,c}$

^a Data are shown as the mean $\pm$ the standard error of the mean; the number of observations is in parentheses. ^b Significance: $p < 0.01$ versus vein. ^c Significance: $p < 0.05$ versus unstented graft.

The results demonstrated that grafting led to an increase in vessel wall thickness accompanied by an increase in DNA concentration per millimeter of length. Thus hyperplasia of smooth muscle cells contributed to the increase in wall size. Nevertheless, the DNA concentration per milligram of wet weight fell, which implies that hypertrophy of cells and laying down of extracellular matrix also took place. Stenting with relatively rigid polytetrafluoroethylene had little net effect on wall thickening because lesser medial thickening was accompanied by greater intimal thickening. Stenting resulted in a reduction in DNA concentration per millimeter of graft length, which implies that less hyperplasia occurred and is consistent with the concept that wall tension is a determinant of hyperplasia. Stenting was also accompanied by a reduction in DNA concentration per milligram of wet weight, which implies that stented grafts had a relatively greater degree of hypertrophy or deposition of extracellular matrix. Owing to the restricted expansion of the stented grafts, the external radius of grafts was reduced by stenting. This together with a greater degree of intimal thickening resulted in greater encroachment into the vessel lumen and a reduction in residual luminal size. Stenting therefore increased predicted mean shear stress at the endothelial surface, although based on previous studies, this is associated with less rather than more intimal proliferation in both arteries [12] and arteriovenous bypass grafts [11]. Alternative explanations for the greater intimal thickening we observed are that preventing graft expansion forced smooth muscle cells into the intima physically, or that interruption of regrowth of adventitial vessels may have caused greater hypertrophy, consistent with previous work [13].

Two other studies [14, 15] have examined the effect of external stenting on vein graft adaptation to the arterial circulation. Barras and colleagues [14] demonstrated that stenting decreased intimal thickness in a sheep model. The number of animals studied was small, however, and different animals were used for test and controls. In addition, the much thinner jugular vein was used, and the grafts were not pressure fixed. Perhaps for these

reasons, Barras and colleagues were unable to locate the internal elastic lamina and therefore measured intimal thickness as the distance from the subendothelial basal lamina to the beginning of the elastic external layer, which is equivalent to total wall thickness in our study.

Kohler and colleagues [15] examined the effect of rigid external support on a rabbit model of arteriovenous bypass grafts. They also were unable to distinguish between the media and intima, but concluded that stenting did not reduce overall wall thickness. In agreement with our study, greater luminal encroachment occurred in the stented grafts, and this led to a smaller final luminal size. The study of Kohler and colleagues [15], however, was compromised by the fact that the proximal part of the graft was wrapped with polytetrafluoroethylene and the distal part of each graft was left to act as the corresponding control. The wrapping of the proximal part of the graft may have altered the local flow dynamics and may have influenced the degree of wall thickening in the control section. We confirmed that contralateral stented and unstented grafts had similar flow patterns, and so the differences between stented and unstented grafts are unlikely to result from differences in initial flow patterns.

In conclusion, this study demonstrates that although external support leads to a reduction in smooth muscle hyperplasia, intimal thickening is promoted. This suggests that other factors such as constraining expansion of the vessel, greater shear stress, or interruption of the adventitia by the stent are also important determinants of wall thickening. The balance of factors is such that stenting of grafts leads to reduced luminal size. If directly applicable to the clinical situation, our results suggest that stenting is unlikely to increase long-term graft patency.

Completion Pneumonectomy and Thoracoplasty for Bronchopleural Fistula and Fungal Empyema

Joe R. Utley, MD

Division of Cardiac Surgery, Spartanburg Regional Medical Center, Spartanburg, South Carolina

Achieving sterilization of the postpneumonectomy space and bronchial healing may be difficult when active granulomatous infection of the pleural space and lung parenchyma is present at the time of operation. Three patients with chronic bronchopleural fistula, fungal empyema, and fungal cavities of the remaining ipsilateral lobe were managed with one-stage completion pneumonectomy and modified eight-rib thoracoplasty. Two patients had infection with *Aspergillus fumigatis* and 1 patient had *Coccidioides immitis*. Two patients had received mediastinal radiation after prior upper lobectomy for carcinoma of the lung. Two patients were having massive hemoptysis at the time of pneumonectomy.

Eight-rib thoracoplasty with suturing of the intercostal muscles to the bronchial stump was performed on all patients. In 2 patients a mass closure of hilar vessels and bronchus was used because of inability to individually close the vessels and bronchus due to ligneous scarring of the hilum. Antibiotic and antifungal irrigations into the operative area were used postoperatively. Chest tubes were left in place 6 to 8 weeks. All wounds healed primarily. Patients were alive without recurrent local infection or tumor at follow-up 3 to 13 years postoperatively.

(*Ann Thorac Surg* 1993;55:672-6)

Achieving bronchial stump closure and control of pleural space infection is often difficult when pneumonectomy is performed in the presence of both pleural space and lung parenchymal granulomatous infection [1]. Experience with completion pneumonectomy for benign conditions has shown that the mortality and morbidity is high. The Mayo Clinic found 27.6% mortality and major complications in 55.2% of patients when completion pneumonectomy was performed for benign disease. The principal causes of death were related to uncontrolled hilar hemorrhage at the time of operation and multiorgan system failure after persistent pleural space infection postoperatively. The Mayo Clinic group postulated that muscle transposition to reinforce the bronchial stump and obliterate the pleural space might contribute to reducing the mortality [2].

We have performed completion pneumonectomy and simultaneous eight-rib thoracoplasty in 3 patients with postlobectomy bronchopleural fistula, fungal empyema, and active fungal infection of the remaining lobe. The purpose of this report is to describe the surgical techniques and management of these patients. The surgical techniques included methods for controlling the hilar vessels, reinforcing the bronchial stump, and obliterating the pleural space.

Patients and Methods

The characteristics of the 3 patients are shown in Table 1. All patients had persistent fungal infection in the empyema cavity and in cavities in the remaining lobe that was

refractory to antifungal therapy. Two patients had the additional complication of massive hemoptysis from empyema, lung cavities, or both. Two patients had received hilar and mediastinal radiation. In every patient no alternative to pneumonectomy was considered a satisfactory option in managing the infection or hemoptysis.

The extensive fungal infection of the empyema cavity and the remaining lung made sterilization of the postpneumonectomy space virtually impossible. Tissue coverage of the bronchial stump was considered desirable to achieve healing of the bronchial closure. Thoracoplasty was performed to obliterate the pleural space and to cover the bronchus with viable muscle.

In 2 patients the effects of radiation and fungal infection had produced such ligneous scarring and induration of the hilum of the lung that individual ligation and closure of pulmonary vessels and bronchus was found to be impossible. The techniques used for closing the vessels and bronchus, performing the modified eight-rib thoracoplasty, and covering the bronchus with intercostal muscle are shown in Figures 1 through 7. The entire hilum is transfixed with multiple mattress sutures of 3-0 Prolene (Ethicon, Somerville, NJ). As the pulmonary artery and vein are divided they are oversewn with running 3-0 Prolene. The bronchus is oversewn with interrupted 3-0 Prolene. Additional sutures are placed in the tissue surrounding the bronchial stump. Decortication of the parietal pleura is performed.

Ribs one through eight are removed subperiosteally from the costovertebral junction to just lateral to the articulation with the cartilaginous ribs. The extent of rib resection and the number of ribs resected are determined at the time of operation. Sufficient ribs are removed to allow collapse of the chest wall against the mediastinum

tube drainage. All patients received amphotericin solution through the irrigation catheter. The chest tubes were slowly removed after the drainage diminished, the consistency cleared, and absence of cavity formation was demonstrated by chest roentgenography and sinograms through the chest tubes. All wounds healed primarily, and no secondary drainage of abscesses or fluid collections was required.

Results

Patients were followed up 3 to 13 years. There was no recurrence of tumor in the 2 patients whose original resection was for carcinoma of the lung. There was no recurrence of infectious complications in the hemithorax. There has been no evidence of infection related to the gutter created by retention of the transverse processes of the vertebrae. One patient required bronchoscopic re-

Fig 4. The upper portion of the figure shows that the bronchus has been divided. In the lower portion the stump of the bronchus has been closed with interrupted 3-0 Prolene. These sutures are left long so that they may be used to secure the intercostal muscles to the bronchus after the modified eight-rib thoracoplasty.

Fig 5. Sutures of 3-0 Prolene are placed in the tissue surrounding the bronchial stump. These sutures will be passed through the intercostal muscles to secure the muscle to the bronchus.

removal of a Prolene mattress suture from the bronchial stump 3 years postoperatively. Figures 8 and 9 show the posteroanterior chest roentgenogram of patient 1 before the operation and 6 months after the operation.

Comment

In the Mayo Clinic experience with completion pneumonectomy, operative death caused by uncontrollable hem-

Fig 8. This is the preoperative posteroanterior chest roentgenogram of patient 1. There is air in the fungal empyema at the apex of the right pleural space. The remaining lower lobe contains numerous cavities.

orrhage typically occurred in patients with benign disease who had previous mediastinal radiation and obliteration of the pericardial space [2]. Others have recommended intrapericardial control of the difficult pulmonary artery at the time of completion pneumonectomy [3, 4]. My colleagues and I chose not to explore the pericardial space because of concern that we might spread the fungal infection to the pericardial cavity. Obliteration of the pericardial space is common in patients having comple-

Fig 7. The left side of the figure shows the bronchial and peribronchial sutures being passed through the intercostal muscles. The sutures are passed through three adjacent intercostal muscle bundles. The right side of the figure shows the position of the intercostal muscles after the bronchial and peribronchial sutures have been tied.

Fig 9. The chest roentgenogram of patient 1 6 months after operation shows complete obliteration of the right pleural space. The left lung has remained free of active infection.

tion pneumonectomy [2]. The technique of closure of the hilum of the lung with horizontal mattress sutures that we describe has the advantage of being applicable in virtually every situation without opening the pericardium.

Thoracoplasty for the management of postpneumonectomy empyema has been recommended by several authors in recent years [5, 6]. Some authors have recommended leaving the first rib but resecting the costovertebral articulation and portions of the transverse processes of the thoracic vertebrae [6]. We chose to resect the first eight ribs including the first rib but to leave the costovertebral articulation undisturbed. Tube drainage of the pleural space after thoracoplasty is recommended for several weeks [6]. The pleural space was completely obliterated in all our patients with the costovertebral junction left intact. It is our impression the complete obliteration of the space is facilitated by prolonged tube drainage along with continuous antibiotic and antifungal irrigation.

We were impressed by the progressive clearing of the drainage from the collapsed pleural space as antibiotic and antifungal solutions were continuously irrigated into the area. Other authors have recommended the local irrigation of antifungal solutions after pulmonary resection for aspergillosis [7]. The radiation effects and scarring of the mediastinal pleura may delay the healing and obliteration of the space and diminish the local concentrations of systemic antibiotics and antifungal agents.

Physical deformity and incapacity due to chest wall changes have not been severe in our patients. One of our patients returned to full-time employment and has been capable of fairly strenuous activities including skiing. The degree of function in these patients has been comparable with the functional state we have observed in patients after intrathoracic transposition of extrathoracic muscle for closure of bronchial fistulas. The blood loss associated with these operations was not excessive. Use of the electrocautery has greatly diminished the blood loss associated with thoracoplasty in my experience. Recent experi-

ence with intrathoracic muscle transposition after pneumonectomy shows that patients require multiple procedures (1 to 19; median, 5). Failure to achieve chest wall healing and bronchial closure was common (16% and 14.3% respectively) after intrathoracic muscle transposition [8]. In my opinion, the thoracoplasty closure technique herein described is a more certain method of obliterating infected thoracic spaces and achieving chest wall healing and bronchial closure than is transposition of muscle. Prolonged tube drainage with instillation of antimicrobials into the infected space is important in achieving these results.

Cardiopulmonary Bypass Procedures in Dialysis Patients

Wilson Ko, MD, Karl H. Kreiger, MD, and O. Wayne Isom, MD

Division of Cardiothoracic Surgery, Department of Surgery, The New York Hospital-Cornell University Medical College, New York, New York

To determine the operative outcome of chronic renal failure patients, we retrospectively reviewed twenty-five consecutive adult patients with chronic renal failure dependent on maintenance hemodialysis (21) or peritoneal dialysis (3), who underwent cardiopulmonary bypass procedures over a five-year period in our institution. The operations included isolated coronary artery bypass grafting in 16 patients; aortic valve replacement in 3; aortic valve replacement plus mitral valve replacement in 1; aortic valve replacement, mitral valve replacement, and coronary artery bypass grafting in 2; aortic valve replacement and coronary artery bypass grafting in 1, mitral valve replacement and coronary artery bypass grafting in 1, and repair of a thoracoabdominal aortic aneurysm in 1 patient. Fourteen operations were elective, and 11 were urgent or emergent. The number of patients with good (>0.50), fair (0.30 to 0.50), and poor (<0.30) left ventricular ejection fractions were 13, 9, and 3, respectively. There were 0, 7, 7, and 11 patients in New York Heart Association functional classification I, II, III, and IV, respectively. All patients were dialyzed within 24 hours before operation. All but 3 patients were managed by immediate postoperative peritoneal dialysis via a Technoff catheter placed intraoperatively (18 patients) or via a preexisting Technoff catheter (4 patients). This

was then switched to hemodialysis when clinical conditions stabilized. Univariate analysis of 22 preoperative and intraoperative variables, followed by a multivariate analysis with a stepwise logistic regression model, was performed using the 30-day or in-hospital operative mortality as the dependent variable. The urgency of the operation and New York Heart Association class IV were found to be independent variables associated with increased operative mortality. There were no operative deaths among the 14 patients having elective operation; 4 of the 11 patients having nonelective operation died postoperatively, constituting a 36% operative mortality for this subgroup. All operative deaths occurred in the patients in preoperative New York Heart Association class IV (4/11 or 36%). This study demonstrated that elective cardiopulmonary bypass operations can be performed in chronic renal failure patients with excellent operative outcome, when done with careful perioperative management. Patients having nonelective operations and patients in the most advanced stage of their cardiac diseases had substantial operative mortalities in this series. The overall operative mortality of the 296 cases reported in the English-language literature thus far is 9%.

(*Ann Thorac Surg* 1993;55:677-84)

The feasibility of general surgical procedures has been demonstrated in patients with chronic renal failure [1, 2]. In the procedures that require the use of cardiopulmonary bypass (CPB), the problems in the management of their perioperative care are accentuated and unique problems arise. Special attention is needed to address the ongoing problems in the balance of fluid and electrolytes, the maintenance of adequate red cell mass, perioperative bleeding diathesis, and the timing and route of perioperative dialysis. Since the first report of valvular operations done on 2 patients with renal failure in 1968 [3], 30 subsequent reports on a variety of cardiopulmonary surgical procedures done on these patients have been published in the English-language literature [2-32]. A total of 278 cases has been reported in the literature thus far, and we report an additional 25 adult dialysis-dependent pa-

tients who underwent operative procedures that required the use of CPB over a 6-year period in our institution. The morbidity and mortality of our series are presented in conjunction with a literature review. The emphasis of this article is on the perioperative management of the dialysis patient who undergoes a CPB procedure.

Patients and Methods

In the period 1985 to 1991, 25 patients had a preoperative diagnosis of chronic renal failure during their hospital stays for any CPB procedures according to the computer data files of the medical record department of The New York Hospital-Cornell University Medical Center. These charts were reviewed in detail regarding the preoperative data, as well as the operative and postoperative course. Coronary artery stenosis was considered clinically significant when more than 75% of the lumen was occluded. Left ventricular ejection fraction was obtained from the cardiac catheterization or radionuclear cineangiography reports. The operations were considered elective when the patients were admitted to the cardiothoracic surgery ser-

Accepted for publication June 22, 1992.

vice electively to have their operations on the following day. They were considered nonelective if the patients were receiving intravenous nitroglycerin or heparin for unstable angina, or requiring inotropic agents or mechanical ventilatory support for cardiopulmonary instability in the preoperative period.

Perioperative factors that were analyzed for their association with operative mortality included sex; age; the type of operation (coronary artery bypass grafting [CABG], valvular replacements, or CABG with valvular replacements); urgency of operation; left ventricular ejection fraction; preoperative New York Heart Association (NYHA) functional classification; previous myocardial infarction; arrhythmia; hypertension; diabetes mellitus; cerebrovascular disease; peripheral vascular disease; chronic pulmonary disease; smoking history; gastrointestinal diseases; preoperative ongoing infection; hematologic disease; lengths of anesthetic, cardiopulmonary bypass, and aortic cross-clamp times; postoperative transfusion requirement; the volume of postoperative mediastinal bleeding; and the need for mediastinal reexploration.

Patients with major hypertension and chronic obstructive pulmonary disease included any receiving long-term medications. Patients with cerebrovascular disease included all with a history of strokes or transient ischemic attacks, and those with peripheral vascular disease included only patients with a history of claudication or peripheral vascular operations (or both). All patients underwent standard cardiopulmonary bypass with a Cobe membrane oxygenator (Cobe Laboratories, Inc, Denver, CO) at moderate hypothermia (25° to 28°C), with pump flow rates of 1.8 to 2.2 L · min⁻¹ · m⁻² to maintain venous oxygen saturation greater than 60% and perfusion pressures greater than 50 mm Hg. The extracorporeal circuit was routinely primed with isotonic crystalloid solution (Normosol; Abbott Laboratories, North Chicago, IL), and fresh blood was added to maintain a minimum hematocrit of 0.24. Myocardial protection was achieved by cold sanguineous hyperkalemic solution and topical cooling with iced slush or cold saline solution. An autotransfusion device (Cell Saver; Haemonetics Braintree, MA) was used to concentrate suctioned mediastinal blood during operation. Patients were rewarmed to a bladder temperature of at least 35°C before the discontinuation of CPB. Operative mortality included deaths occurring within 30 days of the operation or during the same hospitalization.

Fisher's exact test was used for the nonparametric variables, and unpaired *t* test was used for continuous variables in the univariate analysis. All the variables that were associated with operative mortality with a *p* value less than 0.10 were entered into a multivariate logistic regression analysis with stepwise elimination, and coefficients were computed by the method of maximum likelihood. A *p* value less than 0.05 was considered to be statistically significant. Continuous variables are presented as means ± standard deviation when appropriate. Analysis was performed using the BMDP statistical software package (BMDP Statistical Software, Inc, Los Angeles, CA) on a PC-type computer. Literature review was

searched through the Medline files dated back to 1960 in the National Library of Medicine using the modem-operated software Grateful.Med (Bethesda, MD). This was supplemented by the references of the identified articles.

Results

These 25 patients had at least 1 month of dialysis with a mean duration of 33 months before their operative procedures (Table 1). Three patients were maintained on chronic ambulatory peritoneal dialysis, and the others on hemodialysis. The preoperative NYHA classification and

Fig 1. Correlation of postoperative serum potassium level with amount of infused cardioplegic potassium. (CPB = cardiopulmonary bypass.)

left ventricular ejection fraction are listed in Table 1. The NYHA classification of the patient with the thoracoabdominal aortic aneurysm repair is not included. About half of the operations were elective, and the procedures were predominantly CABG. The number of coronary conduits placed ranged from 1 to 5, with a mean of 2.6. The aortic cross-clamp time ranged from 17 to 155 minutes with a mean of 57 minutes, depending on the complexity of the procedure. Cardiopulmonary bypass was used without cardioplegic arrest in the patient with the thoracoabdominal aortic aneurysm repair. A variety of associated diseases are listed in Table 1, with hypertension being the most common. Anemia was, as expected, found in all of these patients due to their renal failure. Polycystic kidney disease ($n = 5$) and diabetes ($n = 4$) are the two most common causes of renal failure in this group of patients. Other causes included hypertension (2 patients), membranous glomerulonephritis (2), renal artery disease (1), poststreptococcal glomerulonephritis (1), and unknown (4). Five patients had chronic renal failure caused by acute tubular necrosis secondary to prerenal causes and contrast toxicity (3 and 2 patients, respectively).

The total amount of potassium given in the cardioplegic solution during operation did not correlate with the serum potassium measured upon arrival to the intensive care unit from the operating room (correlation coefficient = 0.14) (Fig 1). The zero data point represents the patient with the thoracoabdominal aortic aneurysm repair without cardioplegic arrest. This information could not be accurately obtained from the records of 5 patients. There was always a net decrease in the immediate postoperative serum potassium level as compared with the preoperative values (4.56 ± 0.15 mEq/L preoperatively versus 3.91 ± 0.12 mEq/L postoperatively; $p = 0.0016$ by paired t -test). The immediate postoperative serum potassium level also did not correlate with the total anesthesia length (range, 3.4 to 13.3 hours), CPB time (range, 35 to 266 minutes), or aortic cross-clamp time (range, 17 to 155 minutes), with correlation coefficients of 0.22, 0.20, 0.28, respectively.

A total of 10 major and 8 minor complications occurred in these 25 patients (Table 2). Two of the 3 patients with a history of cerebrovascular disease suffered postoperative strokes that were ultimately the cause of their demise. There were three major gastrointestinal complications, two of which required surgical resection for a dead intraabdominal viscus. One of these 2 patients died. One patient with upper gastrointestinal hemorrhage was successfully treated with conservative management. Surprisingly, there were only two minor primary infectious complications (see Table 2) and there were no cases of sternal wound infection.

Postoperative mediastinal bleeding in excess of 1 L in the first 12 hours developed in 1 patient, who was taken back to the operating room for reexploration. The amount of postoperative blood loss and transfusion requirements of these 25 renal patients were compared with that of a cohort of 30 consecutive patients who underwent elective isolated CABG in 1989 (Table 3). The renal patients had similar amounts of blood loss in the first 12 and the second 12 hours after leaving the operating room. Although not statistically significant, the number of units of red cells used was higher in the renal group than the control group. More importantly, the proportion of patients requiring the perioperative use of red cell transfusion was significantly higher in the renal group than in the control group. This was due to the more frequent intraoperative use of red cells, because the preoperative hematocrit was significantly lower in the renal group than in the control group (0.31 ± 0.04 versus 0.41 ± 0.05 , respectively; $p < 0.05$ by unpaired t test). Likewise, the frequencies of platelet and fresh frozen plasma uses were significantly higher in the renal group than in the control group (see Table 3).

The median lengths of intensive care unit, telemetry unit, and postoperative hospitalization stays for these patients were 3 days (range, 1 to 70 days), 8 days (range, 0 to 37 days), and 16 days (range, 11 to 100 days), respectively.

There were a total of four operative deaths. One oc-

curred in a 60-year-old man who underwent urgent three-vessel CABG for unstable angina that required preoperative intravenous nitroglycerin. This patient died of sepsis secondary to acalculous gangrenous cholecystitis despite aggressive surgical treatment. There were 2 patients with a history of strokes who underwent urgent CABG, also for unstable angina. Both of these patients suffered a massive stroke in the postoperative period from which they became comatose and eventually died in the hospital after multiple infectious complications. The last death occurred in a patient who underwent aortic valve replacement, mitral valve replacement, and CABG for recurrent flash pulmonary edema while in the hospital. This patient did well for the first 10 postoperative days, then suffered an unexplainable cardiac arrest. Despite a successful resuscitation after this episode, his general condition progressively deteriorated and he finally died of sepsis after 3 months of hospitalization. All four deaths occurred in patients classified in NYHA class IV who underwent urgent operations (Table 4). Univariate analysis of the 22 perioperative variables followed by a stepwise logistic regression analysis revealed that preoperative NYHA class IV status and nonelective operations were independent predictors of operative mortality.

Comment

There is perhaps no other operative procedure that induces the enormous fluid shifts in the different body compartments as CPB procedures. The success of these demanding procedures depend partly on the ability of the kidneys to handle the rapid and voluminous fluid shifts in the perioperative period. In the absence of renal function, the tolerance of CPB is conceivably reduced. In addition to the immediate problems in the management of fluid and

electrolytes during CPB operations, the uremic patients also have a number of chronic conditions that predispose them to increased operative morbidity and mortality. These include their inability to excrete certain medications, bleeding diathesis secondary to coagulation defects and platelet dysfunction, and susceptibility to infection.

These potential problems explain the paucity of CPB procedures performed in dialysis patients until recently. In the early years of cardiac surgery, only sporadic cases were reported (Table 5). In the last 5 years, however, relatively larger series have been reported from the University of Alabama at Birmingham [27], University of Minnesota [28], Cleveland Clinic [29], University of Pennsylvania [30], Loyola University [31], and Mayo Clinic [32] with operative mortalities ranging from 3% to 16%. The increase in the number of reported cases in the recent years is likely related to the improved techniques in CPB and perioperative care. We now report an additional 25 cases performed during this period in our institution with an overall operative mortality of 16%. The discrepancies in the operative mortalities among these recent series are certainly related to other factors of comorbidity and the types and urgency of the operations. Taking all the reported cases that we managed to retrieve in the English-language literature since the advent of CPB, the overall operative mortality including the cases in the present study is 9% (see Table 5). The operative mortality of 7 patients in one series was not reported and therefore is not included in the calculation of the mortalities. The operative mortalities for the isolated CABG procedures, valvular operations, combined CABG with valvular operations, and thoracic aortic operations were 9% (20/236), 12% (6/47), 13% (1/8), and 0% (0/5), respectively. These data may serve as a guide in future decision making in the management of the chronically dialyzed patients.

^a Combined CABG and VR. ^b Aortic operations. ^c May contain some of the same patients, as reports are from the same group. ^d Unclear mortality.

CABG = coronary artery bypass grafting; VR = valvular replacement.

The special management of uremic patients begins in the preoperative period. Some authors recommend dialysis more than 24 hours before the CPB procedure [9], whereas others recommend to have dialysis as close to the procedure as possible [6]. The argument for the former is to avoid hemodynamic instability that may arise immediately after dialysis, and the latter is to provide the most optimal fluid and electrolyte balance at the time of operation. In addition, one group advocated the use of intraoperative dialysis based on the experience of 1 case [18]. In our group, all patients were dialyzed the day before the operation by their usual route, hemodialysis or peritoneal dialysis. We have no experience of intraoperative dialysis and do not see its necessity. If not already present, a peritoneal dialysis catheter was always placed at the time of the operation under general anesthesia unless there

was a contraindication. Two patients had previous laparotomy, and the catheter could not be placed satisfactorily in 1 patient. Peritoneal dialysis was initiated immediately upon arrival to the intensive care unit to relieve the fluid load and to maintain a normal serum potassium level. The components of the dialysate and the rates of infusion and drainage were varied depending on the fluid and electrolyte status of the patient. Peritoneal dialysis was continued for the first 7 postoperative days, then switched to hemodialysis for those who were dependent on this mode of dialysis preoperatively. The catheter was removed before their hospital discharge for these patients. Antibiotic, usually first-generation cephalosporin, was routinely added to the peritoneal dialysate, and a sample of the drained fluid was cultured for organism daily as long as the catheter was in place.

The use of peritoneal dialysis has advantages over hemodialysis in the postoperative period. The administration of peritoneal dialysis is convenient with minimal equipment requirement and does not require a specialized technician. It can be initiated any time the surgeon deems it necessary without waiting for the dialysis team. Most importantly, it avoids the hemodynamic instability and the risk of heparin-associated bleeding associated with the use of hemodialysis; for these reasons, we have been able to begin dialysis immediately after operation.

The chronic anemia and bleeding tendency of the renal failure patients obligate them to a greater requirement of transfusion of blood products in the perioperative period of CPB operations that require full heparinization. Some authors recommend the use of preoperative red cell transfusion in this patient group because of their chronic anemia [10]. We routinely do not transfuse these patients preoperatively to elevate their normal level of red cell mass, in anticipation of the need for hemodilution during CPB. We do anticipate a greater need of red cell transfusion in the operating room and in the postoperative period. As demonstrated in Table 3, the blood product requirements of this group of renal patients were in fact greater than that of a cohort of elective patients with normal renal functions; a much greater proportion of the renal group needed red cell, platelet, and fresh frozen plasma transfusion than the control group. The greater number of units of red cell transfusion in the renal group was not due to greater mediastinal blood loss after sternal wound closure (see Table 3). The greater number of units of red cells used reflected more intraoperative usage, which was due to lower preoperative hematocrit levels and more intraoperative blood loss. Although as much of the blood loss that occurred in the operating room as possible was returned to the patient after a saline wash and centrifugation by the Cell Saver, a considerable amount of hemolysis can be expected from the negative pressure suctioning of pooled blood in the mediastinum and the processing in the Cell Saver. The hematocrit of these patients is usually kept greater than 0.24, as these patients are physiologically adjusted to chronic anemia.

The greater use of platelets and fresh frozen plasma again reflected the difficulty in achieving hemostasis after the discontinuation of CPB in the operating room. The renal patients have been shown to have platelet dysfunction and not so well characterized coagulation defects. Their platelets have been shown to have adhesion and aggregating deficiencies, and they have a factor III deficiency [34]. Although not routinely used, intraoperative platelet and fresh frozen plasma were much more frequently needed to achieve hemostasis before the sternal wounds were closed in these renal patients (see Table 3). Once hemostasis was deemed adequate, however, there did not appear to be greater postoperative blood loss in the first 24 hours. The use of these products at the end of the operation is always decided on by the operator without much objective data other than the activated clotting time and the amount of bleeding that is occurring at the time. Other coagulation studies and platelet counts require much time to perform and therefore would not be

useful in the operating room. We currently do not see an alternative to assess the coagulation status more accurately, which would theoretically minimize the use of blood products such as platelets, fresh frozen plasma, and cryoprecipitate.

Desmopressin acetate has been shown to decrease intraoperative and postoperative bleeding and transfusion requirements in patients undergoing "complex" or prolonged cardiac operations and also in patients who have an increased rate of mediastinal hemorrhage after CPB [35]. However, we were not able to show any benefits in postoperative mediastinal blood loss, transfusion requirement or platelet function by using desmopressin acetate in routine elective CABG cases [33]. We subsequently have discontinued its routine use in CPB surgery. The use of desmopressin acetate has been shown to improve bleeding time (a measure of platelet function) in uremic patients [36]. It would be interesting to determine if the routine use of desmopressin acetate after the discontinuation of CPB may reduce the requirement of blood products and mediastinal bleeding in the dialysis patients.

The most important electrolyte imbalance in CPB operations is that of potassium because elevated and reduced levels are associated with life-threatening arrhythmia, especially after ischemia. The sources of potassium during operation include tissue trauma from surgical manipulation, hemolysis from the bypass run, transfusion of red cells, and most notably the hyperkalemic cardioplegic solution. The concern of hyperkalemia from CPB operations, however, may be alleviated from the data shown in this study. There was in fact no correlation between the post-CPB serum potassium level and the amount of infused cardioplegic potassium, the length of bypass run, or the length of anesthesia time which would reflect the complexity or the degree of surgical trauma. On the contrary, there was a consistent and significant decrease in the serum potassium level as first measured postoperatively compared with the pre-CPB value; this was presumably caused by the process of hemodilution during CPB.

The renal failure patients are prone to infection, and this propensity is attributed to detectable leukocyte dysfunction in terms of chemotaxis and leukopenia [34]. In this series of 25 patients, there were only two incidents of minor postoperative infection and no sternal wound infection. Larger series will be needed to detect this potential problem. The patients in this group received perioperative prophylactic antibiotics as did other patients. The absence of renal function and the mode of dialysis at the time of administration need to be taken into account in the antibiotic doses as with all other medications.

A small but ever-present incidence of post-CPB gastrointestinal complications occurs with considerable hospital mortality as reported by our group [37, 38]. The incidence of intraabdominal ischemic viscus in this series appears high (2/25) as compared with that of the general cardiac surgery patient population in our institution [37]. It has been reported that accelerated atherosclerosis develops in renal failure patients on chronic dialysis [39]. It is plausi-

ble that the ischemic viscus was a consequence of a low flow state during CPB that was exacerbated by atherosclerotic mesenteric arteries in these patients. Perhaps higher bypass flow rates or higher perfusion bypass pressure may prevent this type of catastrophe.

The chronic arteriovenous fistulas of the renal patients are at risk for thrombosis in the operating room from applied pressure and perhaps during the low flow state. Six of 58 patients undergoing general surgical procedures in one series had this complication, and the authors of that series recommend using low-dose heparin solution infused into the fistulas [2]. This would not be necessary during CPB with full heparinization. We ensured that the arm with the fistula was well padded and did not have this particular complication.

Prophylactic pericardiectomy is recommended by two groups [16, 21] to prevent postoperative pericarditis, as this is already a common affliction of the renal patients. However, we have not employed this approach and have not had this complication in the renal patients. The use of aspirin has been shown to prolong aortocoronary graft patency [40], and this is routinely employed in our general cardiac surgery patient population. In light of the well-documented platelet dysfunction of the chronic renal patient [34], the risk/benefit ratio in the use of aspirin in this patient population is not clear. However, the pathogenesis of intimal hyperplasia and atherogenesis of bypass grafts involves the endothelium and possibly other cell types in addition to the platelets, and therefore it may be prudent to use aspirin also in the renal patients after CABG.

Two issues need to be addressed regarding valvular replacement in the dialysis patients. There is an obvious concern in the need for lifelong anticoagulation associated with the use of metallic valves in these patients who require frequent percutaneous puncture of their arteriovenous fistula for dialysis. However, there is some anecdotal evidence of premature calcification of tissue valves of these patients, presumably secondary to their imbalance in calcium metabolism [21]. For this reason, we routinely use metallic valves in the renal patients and place them on long-term anticoagulation. Furthermore, hemodialysis is definitely more invasive than dental and endoscopic procedures that normally require the use of prophylactic antibiotics. The need for long-term oral or intravenous antibiotics during hemodialysis on these patients with artificial valves is unclear and will require longer experience of considerably more patients.

Finally, the four operative deaths occurred in patients who were in NYHA class IV and who had urgent operations; these were shown statistically to be two independent predictors of operative mortality. However, the result of this statistical analysis should be viewed with considerable reservation. Three of the four deaths were not cardiac related. The death due to ongoing sepsis secondary to gangrenous cholecystitis was probably only avoidable if the diagnosis of cholecystitis was made earlier, and this was not related to the course of the patient's cardiac disease. There is no documented correlation between the urgency of CPB operation and gastrointestinal

complication. The sudden cardiac arrest that occurred in 1 patient at 5 AM of the 10th postoperative day after an uneventful postoperative course most likely was related to sudden arrhythmia. His ultimate death again was not likely related to the urgency of the operation or the stage of his cardiac disease. The 2 remaining patients who died of their massive postoperative strokes had a history of cerebrovascular disease. They were both operated on urgently. In these 2 cases, one can argue that if cardiac surgical intervention was considered electively earlier in the course of their cardiac diseases, perhaps their cerebrovascular disease could have been evaluated to the extent as to prevent the fatal complication. With the recent availability of color flow Doppler examination, bedside evaluation of the extracranial carotid arteries should be performed in the future even for the patients who are awaiting cardiac operation urgently.

In conclusion, this study demonstrated that elective CPB operations can be performed in chronic renal failure patients with excellent operative outcome when done with careful perioperative management. This requires a collaborative effort among the cardiac surgeon, anesthesiologist, nephrologist, and cardiologist, and significantly longer intensive care units and hospital stays should be expected. Nonelective cases and patients in the most advanced stage of their cardiac diseases had substantial operative mortality in this series. The overall operative mortality of the 296 cases reported in the English-language literature thus far is 9%, and this may serve as a guide in the consideration of surgical intervention of the dialysis patients with cardiac diseases. As shown in this study, the operative risks depend on the urgency of the operation and the stage of the disease. Only with considerably more experience can we better stratify the operative risks and benefits of the various CPB procedures for the renal failure patients with different cardiac diseases.

Batiuk and associates [32] have pointed out that coronary artery disease is responsible for 30% to 53% of deaths among chronic dialysis patients in the United States, Canada, Europe, Australia, and New Zealand. At the end of 1987, 98,400 patients were on chronic dialysis [34]. This number continues to increase because of the ever-improving technology in the mechanics of dialysis. In view of the high incidence of coronary artery disease of these patients with accelerated atherosclerosis, it is surprising that more patients are not referred to surgical intervention. The operative result of our group and the literature reviewed in this article is acceptable. We hope patients and their physicians will consider this option of therapy earlier in the course of the disease when the outcome of surgical intervention is most favorable.

We greatly appreciated the assistance of Daniel Lang, BA, in the chart reviews and data compilation for this study. The attending surgeons of these patients included O. Wayne Isom, MD, Karl H. Krieger, MD, Jeffrey P. Gold, MD, Samuel Lang, MD, and Nasser Altorki, MD, of the Cardiothoracic Surgical Service of The New York Hospital.

Surgical Experience With Defibrillator Implantation Using Nonthoracotomy Leads

Dieter Hammel, MD, Michael Block, MD, Wolfgang Konertz, MD, Martin Borggrefe, MD, Frank Isbruch, MD, Boulos Asfour, MD, Armin Geiger, MD, Günter Breithardt, MD, and Hans H. Scheld, MD

Department of Thoracic and Cardiovascular Surgery and Department of Cardiology, Hospital of the Westphalian Wilhelms University of Muenster, Muenster, Federal Republic of Germany

Between October 10, 1989, and June 17, 1991, 109 patients with life-threatening ventricular arrhythmias received an implantable cardioverter-defibrillator at our institution. In 50 patients, nonthoracotomy lead systems consisting of a subcutaneous chest wall patch electrode near the cardiac apex and one (Cardiac Pacemakers, Inc: Endotak C) or two (Medtronic: Transvene) transvenous electrodes were tested. The mean ejection fraction was 0.44 ± 0.15 with a range from 0.19 to 0.81. Twenty-four patients had a history of open heart operation. In 43 patients the nonthoracotomy lead system was implanted, whereas in 7 patients epicardial patch lead systems were required due to elevated defibrillation thresholds during nonthoracotomy lead testing. There was one perioperative death unrelated to the operative procedure (hydrocephalus

internus). Hemorrhage from the subcutaneous patch pocket or the device pocket that required reintervention occurred in 4 patients. During a mean follow-up of 13 ± 5 months (range, 4 to 26 months) no dislocation of an endocardial lead, insulation defect, or lead fracture has been observed. In 1 patient, the lead system had to be removed due to infection of the subcutaneous patch pocket. The cardiovascular survival rate was 98% at 12 and 18 months, and freedom from sudden cardiac death was 100% at 6 and 12 months. In conclusion, defibrillator implantation using nonthoracotomy lead systems is feasible with a success rate of 86%, and during short-term follow-up no problems related to the lead system such as dislocation, fracture, or insulation defect have occurred.

(*Ann Thorac Surg* 1993;55:685-93)

The automatic implantable cardioverter-defibrillator (ICD) has been shown to be an effective tool in the treatment of drug-refractory sustained ventricular tachycardia/ventricular fibrillation and in survivors of sudden cardiac death who have a significant risk of recurrence. Mortality due to arrhythmias is greatly diminished in patients with ICDs. The reported incidence of sudden cardiac death at 1 year of follow-up in patients with the ICD is 1% to 4.6% [1-7]. Historical controls showed an incidence of recurrent sudden death in cardiac arrest survivors of 20% to 30% at 1- to 2-year follow-up [8, 9]. In view of these data, the ICD might be the first-line therapy of survivors of sudden cardiac death [10].

However, device and lead system insertion is associated with a defined morbidity and mortality, mainly related to any kind of thoracotomy that is required for placement of one or more defibrillation electrodes [1, 2, 5, 6, 11]. A number of complications that caused serious morbidity have been noted. The major problem encountered has been infection in 1% to 20% of the patients [1, 2, 5, 6, 11] with the necessity of explantation of the system. Other periprocedural complications include pneumonia, venous thrombosis, large pericardial and pleural effu-

sions, myocardial infarction, coronary artery laceration, and late constrictive pericarditis [12].

Defibrillator implantation in patients with a prior cardiac operation is complicated by periepicardial adhesions. Using a lateral thoracotomy and extrapericardial patch placement in combination with endocardial sensing leads may eliminate this difficulty in most cases. But in patients in whom the pleural space was opened during the prior operation (eg, after harvesting internal mammary artery grafts), difficulties caused by pleural adhesions may arise using this approach, and a higher incidence of pulmonary problems using this approach has been reported [5]. Patients with coronary artery disease who may require coronary artery bypass grafting in the future are at higher risk for perioperative complications during a later open heart procedure due to destruction of the epicardial landmarks. Thus, minimizing the implantation procedure—by avoiding thoracotomy—should lead to a reduction in morbidity and mortality.

The endocardial approach to internal defibrillation is not new. Hopps and Bigelow [13] did the first work on the concept of transvenous defibrillation. Mirowski, one of the inaugurators of ICD therapy, demonstrated the effectiveness of catheter defibrillation in the early 1970s [14]. Due to lower defibrillation thresholds, the most routinely used lead systems consisted of at least one epicardially or pericardially placed defibrillation patch electrode until recently. In 1987, the first nonthoracotomy lead system

Accepted for publication June 23, 1992.

(Endotak; Cardiac Pacemakers, Inc [CPI], St. Paul, MN) was implanted in a small number of patients. Due to lead fractures during the follow-up, implantation was stopped to improve the leads [15-17]. A second transvenous lead system (model 6884 + 6881; Medtronic, Minneapolis, MN) was tested but not implanted in patients who received a defibrillator with epicardial lead placement in 1989 [18]. At our institution ICD implantation by transvenous subcutaneous approach was started in 1989, initially only in patients with a prior cardiac operation [19, 20].

The purpose of this report is to describe our initial surgical experience with two different nonthoracotomy lead systems in patients who underwent ICD implantation without concomitant open heart procedures.

Material and Methods

Patients

Between October 10, 1989, and June 17, 1991, 109 patients received an ICD at our institution. Approval by the local institutional human research committee has been obtained in August 1989. At the beginning only patients who had had a prior cardiac operation were selected for the nonthoracotomy approach. Before implantation, written informed consent was obtained. The patients had been informed that, in case of insufficient defibrillation by the endocardial approach, epicardial leads would be placed during the same procedure. In September 1990 after data were collected for 13 patients, our policy was changed and the nonthoracotomy approach was used as the method of first choice, except in patients who need concomitant open heart procedures.

Patient Evaluation

Patients were considered as candidates for defibrillator implantation if they had experienced at least one cardiac arrest caused by ventricular tachyarrhythmia or had recurrent sustained, life-threatening ventricular tachycardia. Before ICD implantation, each patient was evaluated with electrocardiography, Holter monitoring, maximal treadmill exercise testing, echocardiography, and left and right heart catheterization. Serial antiarrhythmic drug testing guided by electrophysiologic studies had failed to control ventricular arrhythmias in most patients or antiarrhythmic drug therapy had been withdrawn due to serious side effects of the drugs, and other therapeutic options such as map-guided antitachycardia operation or catheter ablation were not applicable or had failed in controlling the arrhythmias.

Lead Systems and Devices Implanted

Two different nonthoracotomy lead systems with their corresponding devices were implanted. The Medtronic nonthoracotomy lead system consisted of two transvenous leads and a subcutaneous patch electrode. The pulse generator (PCD model 7216A or 7217B; Medtronic) was a newly designed multiprogrammable, third-generation [21], automatic tachyarrhythmia control device. Defibrillation modalities available consisted of one

Fig 1. CPI Endotak C nonthoracotomy lead system: (top) subcutaneous patch electrode (Endotak SQ), (middle) transvenous lead with two defibrillation coils and the porous-tip electrode, (bottom) enlargement of the porous-tip electrode.

(single shock) or two (simultaneous or sequential) high voltage pulses. Two methods of overdrive pacing (burst and ramp) and cardioversion could be selected to terminate ventricular tachycardia. The CPI nonthoracotomy lead system was composed of one transvenous lead (Endotak C) and a subcutaneous patch lead (Fig 1). The pulse generator was a Ventak P 1550 programmable device (second-generation device) with options for cardioversion and defibrillation. The CPI Ventak PRx 1700 (third-generation device) was used instead of the Ventak P 1550 when available. The Endotak C lead has been manufactured with different distances between the right ventricular defibrillation cathode and the right atrial and superior vena caval anodes for use in patients with different sizes of right atria or ventricles.

Operative Procedure

Implantation was done under general anesthesia. Before the surgical procedure, cutaneous self-adhesive electrodes were applied to the chest to defibrillate via an external direct-current defibrillator in case of insufficient internal defibrillation during the test procedure. The preparation of the operative field was done in such a manner that, in case of insufficient defibrillation by the nonthoracotomy leads, epicardial lead placement by a subxiphoid or transternal approach was possible.

Venous access was gained through a phlebotomy of the left cephalic vein or the left subclavian vein or by puncture of the subclavian vein using the Seldinger technique. The endocardial leads were positioned under fluoroscopic control.

The Transvene (Medtronic) right ventricular electrode was a tripolar, endocardial screw-in lead. After positioning in the right ventricular apex the tip was actively fixed with its helical screw. Electrical measurements of pacing and sensing thresholds were performed. If the initial parameters were unacceptable, the ventricular lead was repositioned. The second transvenous lead was placed in

C

Fig 2. Nonthoracotomy lead systems. (A) Medtronic Transvene leads: second transvenous lead (anode 1) placed on the superior atriocaval junction. (B) Medtronic Transvene leads: second transvenous lead (anode 1) placed in the coronary sinus. (C) CPI Endotak leads: anode 1 and subcutaneous patch (anode 2) linked by a Y connector. (ICD = implantable cardioverter-defibrillator.)

the superior caval vein with its tip in the right atrium. In case of poor defibrillation threshold (DFT; minimal successful defibrillation energy ≥ 18 J) this lead could be positioned in the coronary sinus.

The Endotak C (CPI) lead, a porous-tip electrode, was also positioned in the apex of the right ventricle with fluoroscopic guidance. Passive anchoring was achieved by firmly wedging the tip into the trabeculae. Thereafter, pacing and sensing thresholds were determined.

The subcutaneous patch (Medtronic or CPI) was placed on the thoracic fascia near the cardiac apex by an incision in the anterior axillary line. To reduce impedance between patch and chest wall the patch pocket was filled with

isotonic saline solution and temporarily closed. Thereafter, the electrodes were connected to an external test device to measure the DFT.

After sufficient defibrillation had been achieved, a pulse generator pocket was created by a median incision in the epigastrium, the left rectus sheath was opened, and the rectus muscle was separated from the fascia behind until the dimension of the created space allowed tension-free placement of the device. The electrodes were connected to the device by subcutaneous tunnelling from the left delto-pectoral sulcus to the patch pouch incision and then together with the subcutaneous lead to the generator pocket (Fig 2). A final testing was done by telemetry when

Table 1. Electrophysiologic Testing Requirements

Variable	CPI Ventak PRx	Medtronic PCD
R-wave sensing		
Amplitude (mV)	>5	>5
Duration (ms)	<100	...
Slew rate (V/s)	...	>0.75
Pacing		
Threshold (V)	<1.5	<1.0

Defibrillation		
Maximum DFT (J) (accepted)	20	18
Maximum energy (J) (delivered)	34	34

DFT = defibrillation threshold.

the electrodes were connected to the device. Drains were placed in the generator pocket and behind the subcutaneous patch electrode and the wounds were closed in layers.

Just before surgery and on the two following days all patients received intravenously antibiotics (cephamandol) as prophylactic treatment. After a short time of monitoring in the operation theatre, the patients were transferred to the cardiology ward with the device activated.

Intraoperative Electrophysiologic Testing

After proper positioning and anchoring of the right ventricular electrodes had been achieved, measurements of sensing and pacing characteristics were done. R-wave amplitudes greater than 5 mV, slew rates greater than 0.75 V/s, and pacing thresholds less than 1 V with a pulse width of 0.5 ms (impedance between 250 and 800 Ω) were accepted. Due to another arrhythmia detection algorithm, the requirements for the quality of the sensing signals had been less strict when using Ventak devices (Table 1). Instead of a slew rate criterion an R-wave duration in the recorded endocardial electrocardiogram (sensing leads) less than 100 ms was required. Although pacing was not

available in Ventak P 1550 devices, pacing threshold was measured in all patients to avoid problems if later the necessity of antitachycardia or antibradycardia pacing required an exchange of the device.

After the subcutaneous patch had been inserted and the connection of the leads with the external test device had been established, a low-voltage (100 V) synchronized shock was applied during sinus rhythm to ensure correct connections and to determine the resistance of the defibrillation leads. Resistances between 20 and 100 Ω were accepted. Ventricular fibrillation was induced by ramp pacing of the right ventricle or by alternating current (50 Hz).

The test protocols for the Transvene and Endotak leads differed slightly due to different functions of the devices and configurations of the lead system (Table 2). Using an external PCD pulse generator, a sequential shock with an energy of 18 J (550 V) between the right ventricular and the second transvenous electrode and between the right ventricular and the subcutaneous electrode was delivered. If the defibrillation was unsuccessful, a rescue shock was delivered by the external testing device (34 J) or by the external defibrillator with cutaneous patches.

As sequential shock delivery was not a feature of the CPI devices, the endocardial right atrial and subcutaneous electrode were linked by a Y connector. Testing was started with the same configuration as described above for the Medtronic lead system. After induction of ventricular fibrillation/flutter, a 20-J shock was delivered by an external device. If fibrillation continued an additional internal 40-J or an external 360-J rescue shock was delivered.

If the 20 J (Transvene, 18 J) shock was successful, ventricular fibrillation/flutter was defibrillated with decremental energies of 15, 10, and 5 J until the first failure occurred. At least three successes at 20 J or less [18] had to be achieved before the leads were implanted permanently. In case of failure with the first shock delivery configuration and as long as the patient showed no hemodynamic deterioration, several different lead configurations were tested. If no sufficient DFT was obtained with the nonthoracotomy leads, epicardial lead placement

Table 2. System Configuration

Variable	Medtronic	CPI
Sensing/pacing	True bipolar sensing electrode (tip of the RV lead)	Bipolar sensing between RV lead tip and defibrillation cathode
Anchoring	Active (helical screw)	Passive (porous tip)
Defibrillation	RV cathode, 2nd free positionable transvenous lead (SVC, CS)	RV cathode, 2nd, fixed distance transvenous lead (SVC, three distances available)
Patch electrode	Subcutaneous near cardiac apex	Subcutaneous near cardiac apex
Shock modality	Monophasic, sequential or simultaneous between (1) RV lead ² -patch and (2) RV lead-second transvenous lead (no fixed shock modality, current pathways programmable by telemetry)	Monophasic, simultaneous, selection of current pathways possible only during implantation by using a Y connector to establish the lead system

CS = coronary sinus; RV = right ventricular; SVC = superior vena cava.

by a subxiphoid approach or by sternotomy was performed [22].

Postoperative Management and Follow-up

After removal of the drains, in the first 24 patients effective anticoagulation with heparin was started, which was followed by 6 months of coumarin therapy to prevent thrombus formation on the transvenous leads; the last 19 patients received low-dose heparin therapy followed by coumarin or aspirin for 6 months. Internal cardioverter-defibrillator energies for cardioversion/defibrillation were programmed to maximum values (Ventak P: 30 J; Ventak PRx, PCD: 34 J). Before hospital discharge and at regular intervals of at least 3 months the integrity of the leads was ensured by biplane chest roentgenogram and determination of sensitivity and pacing thresholds. Defibrillation was tested before hospital discharge and again after 2 (CPI) or 6 (Medtronic) months. The patients were advised to contact the outpatient clinic in any case of adverse reactions to the defibrillator, if they had noticed a defibrillation shock, or if syncope had occurred.

Data Collection and Statistical Analyses

All data are presented as the mean $\pm$ standard deviation, with range in parentheses. Life-table analysis was performed by the Kaplan-Meier method.

Results

Fifty patients participated in this study. Ten patients were women and 40 were men, with a mean age of 55 ± 13 years (range, 16 to 72 years). The underlying cardiac disease was coronary artery disease in 33 patients, dilative cardiomyopathy in 9 patients, hypertrophic cardiomyopathy in 1 patient, valvular heart disease in 2 patients, arrhythmogenic right ventricular disease in 3 patients, prolonged QT syndrome in 1 patient, and tetralogy of Fallot in 1 patient. The patients' clinical data are listed in Table 3. Mean ejection fraction, as determined from left ventricular angiography, was 0.44 ± 0.15 (range, 0.19 to 0.81). Ten patients were in New York Heart Association class I, 19 patients in class II, and 21 patients in class III. Twenty-four patients had previous open heart procedures. Among the 17 patients who had received coronary artery bypass grafting, 2 had patent internal mammary artery grafts. Other previous cardiac procedures are listed in Table 4.

During intraoperative testing ventricular fibrillation or flutter was induced an average of 6 ± 3 times to determine the DFTs. In 40 patients sufficient defibrillation (DFT ≤ 20 J [CPI] or 18 J [Medtronic]) was achieved by using the transvenous/subcutaneous approach with a mean DFT of 15 ± 4 J, whereas no optimal DFT with nonthoracotomy leads could be obtained in 10 patients. Nevertheless 3 patients with borderline DFTs (<25 J) received permanent implantation of a nonthoracotomy lead system due to some success at 18 J, no failures at 34 J, a prior cardiac operation, and administration of amiodarone at implantation. In the remaining 7 patients epicardial lead placement was done during the same procedure ($n = 5$) or

during a second operation ($n = 2$) with a mean DFT of 16 ± 3 J (epicardial patches). Prolonged cardiopulmonary resuscitation for ventricular fibrillation due to temporarily insufficient defibrillation by internal and external electrodes was the reason for these two-stage procedures. Median sternotomy was used because of better exposure in case of a previous open heart operation (patients 12 and 18), failing defibrillation by subxiphoid approach (patient 41), or necessity of internal defibrillation by paddle electrodes (patient 27). In the other 3 patients a subxiphoid implantation was performed.

The operative procedure lasted 159 ± 63 minutes (range, 90 to 300 minutes). The seven implantations in which the nonthoracotomy approach failed lasted 208 ± 48 minutes (range, 160 to 300 minutes) (in case of two-stage procedures, both operation times were added). The creation of the patch and device pockets were done after achieving sufficient pace/sense thresholds (patch) and defibrillation thresholds (device) early in our experience. During the last 20 procedures, testing and preparation were performed simultaneously to shorten the procedure. The last 10 procedures were performed with a mean operative time of 117 ± 26 minutes.

No intraoperative complications occurred. Postoperatively, there was one death unrelated to the procedure (patient 16) caused by a hydrocephalus internus with consecutive brain death on postoperative day 6. Hemorrhage that required reintervention occurred in 4 patients. Bleeding from an epigastric vessel was the reason for a revision of a device pocket. In another case of patch pocket hematoma, no circumscribed bleeding was found. Two reinterventions were required because of patch pocket hematomas on the eighth day immediately after shock delivery during predischARGE testing (patient 48) and in the sixth week (patient 38) after an initially uneventful postoperative course. In both patients bleeding from chest wall arteries was found. Late infection of the subcutaneous patch pocket occurred in 1 patient (patient 8). In this patient, removal of the whole system was performed without any problem 7 months after implan-

Fig 3. Kaplan-Meier survival curves for patients with nonthoracotomy lead systems. Numbers above points indicate the number of patients available for analysis. (Arrhythmic survival = freedom from sudden cardiac death.)

tation. The endocardial leads were easily withdrawn. Thrombosis of the subclavian vein developed in 1 patient 1 month after implantation. One patient died 4 months after implantation due to progressive heart failure.

There has been no dislocation of an endocardial lead, and pacing and sensing function is proper in all patients but 1. In this patient pacing threshold increased to a level close to exit block (1.04 ms at 5.4 V) while sensing function was not altered. During follow-up, stability of the lead system was 100% at 12 and 18 months.

In all patients ventricular fibrillation/flutter induced at the pre-discharge or follow-up tests was terminated successfully by the ICD. Twenty-two of 43 patients (51%) experienced cardioversion/defibrillation because of spontaneous ventricular fibrillation/flutter episodes 3.4 ± 4 months after implantation. Life-table analysis (Fig 3) indicated 12- and 18-month cardiovascular survival of 98% and a freedom from sudden cardiac death of 100% at 6 and 12 months.

Comment

Our study indicates the practicability of nonthoracotomy lead systems in all patients who need an ICD device without a concomitant open heart operation. Using nonthoracotomy lead systems, an intraoperative defibrillation threshold lower than or equal to 20 J showed a reliable function of the implanted defibrillation device during follow-up.

Forty of our 50 patients who entered the study fulfilled this criterion. Three borderline cases ($20 \text{ J} < \text{DFT} < 25 \text{ J}$) were included due to the fact that all 3 patients received amiodarone during implantation and reduction of the DFT after discontinuation of amiodarone was foreseeable [2, 23]. Thus we conclude that about 86% of ICD implantations without concomitant open heart procedures could be performed with nonthoracotomy lead systems. Studies to predict an insufficient DFT and investigations to improve the effectiveness of this approach are in progress.

Our own experience indicates that the use of amiodarone and low ejection fraction are risk factors for an insufficient DFT and that biphasic shocks will improve DFTs. The mean ejection fraction in our series is higher than in other reported series. One reason may be the inclusion of 4 patients with normal left heart function (3 patients with arrhythmogenic right ventricle and 1 with QT syndrome) in this study.

The advantages of this new technique are evident: due to the minor surgical procedure all patients were extubated at the end of the operation or in the recovery room. Mobilization of the patients was attainable early; in our series all patients were completely mobilized until the second postoperative day. No postoperative pneumonia, which was a serious complication in other series [5], occurred in these patients. Complications such as pericardial or pleural effusions and coronary vessel laceration, which have been observed with thoracotomy and epicardial lead insertion, did not occur after transvenous/subcutaneous lead placement. In patients with coronary artery disease and the probability of future coronary artery bypass grafting (eg, patient 42), difficulties caused by obliteration of epicardial landmarks were avoided [24]. As with all foreign body implantations, infection causes serious problems. Removal of the whole ICD system is required for definitive cure. An incidence of infection of 1% to 20% has been described for epicardial defibrillators. In our series infection occurred in 1 patient (2%), but in contrast to conventional ICD patches, the endocardial and subcutaneous electrodes were easily withdrawn by a minor surgical procedure. Bleeding from the device and the subcutaneous patch pouch was a complication that required reintervention in 4 patients. During the study we have learned that the side branches of the thoracodorsal artery have to be dissected carefully and that no vessels should be left in place between the chest wall muscles and the subcutaneous patch electrode. After paying attention to this point and changing the anticoagulation therapy

(low-dose heparin therapy except in patients with artificial valves), we seem to have solved this problem.

Seven patients in whom nonthoracotomy lead systems did not work received an epicardial patch electrode system, which worked with proper defibrillation thresholds. Prolonged duration of the surgical procedure or the need for a second operation and discomfort by the additional wounds are major disadvantages for these patients. During our study, we have learned to use the sensing capability of the transvenous electrodes in combination with the epicardial patches. This procedure promises better sensing and pacing values and avoids placement of epicardial sensing leads in cases of failed defibrillation by the nonthoracotomy lead system. Thus, this subgroup may also benefit from the placement of nonthoracotomy leads.

Postimplantation failure of the endocardial lead system is a further critical topic to discuss. Dislocation of the right ventricular lead, lead fractures, and insulation defects are of surgical interest. Sensing problems that cause inappropriate shocks during normal rhythm or failure to deliver appropriate therapy are well-known problems in epicardial defibrillation therapy [2, 3, 5, 25]. Insufficient defibrillation shocks due to increased defibrillation thresholds in the follow-up period are also serious complications. In 1988 a small series of Endotak C leads was implanted. The investigation was terminated due to lead fractures and related sudden cardiac deaths [26].

By using the improved CPI and Medtronic leads we have not monitored any lead dislocation, lead fracture, or insulation defect. All implanted systems are working without major problems, and arrhythmic survival has been excellent during a mean follow-up of 13 ± 5 months while arrhythmic events have not been rare. Inappropriate shocks or missing shocks caused by sensing problems have not occurred. The use of endocardial instead of epicardial sensing electrodes may be a possible explanation, as the superiority of endocardial electrodes has been established by bradycardia pacemaker experience [27, 28]. The patient with a PCD pulse generator in whom an increased pacing threshold was monitored during follow-up was not dependent on VVI pacing. As a threshold of 1.04 ms at 5.4 V was monitored, the output of the PCD was set at maximum (1.59 ms at 5.4 V) for reliable antitachycardia pacing. Only permanent VVI pacing at these settings will have a significant negative impact on longevity of the battery; therefore, the patient did not need a revision of the right ventricular lead.

The intention of implanting nonthoracotomy lead systems instead of epicardial leads was a reduction in perioperative morbidity and mortality at the cost of a slight elevation in the DFTs compared with patch lead systems. Our present data cannot demonstrate a significant reduction in mortality or morbidity. The overall complication rate of 14% in this series compares well with epicardial procedures. But, due to the growing experience with the nonthoracotomy lead systems, there is an improvement in the implantation procedure, which leads to a reduction in periprocedural complications. Technical improvements such as biphasic shocks, reduction of the size of the

devices, and a new design of the chest wall electrode will simplify the procedure. In February 1992 the 100th nonthoracotomy implantation was done at our institution, and hopefully we can demonstrate a significant reduction in perioperative morbidity in this greater series after collection of the short-term follow-up data. Up to the time of this report, our short-term follow-up has demonstrated the stability of the nonthoracotomy lead systems and has uncovered no failure of the defibrillation function. A definitive evaluation of the defibrillation capability with the nonthoracotomy lead systems is reserved until the completion of long-term follow-up.

Calprotectin and Complement Activation During Major Operations With or Without Cardiopulmonary Bypass

Peter Garred, MD, PhD, Erik Fosse, MD, PhD, Magne K. Fagerhol, MD, PhD, Vibeke Videm, MD, PhD, and Tom Eirik Mollnes, MD, PhD

Institute of Immunology and Rheumatology, the National Hospital; Section of Thoracic and Cardiovascular Surgery, Department of Surgery, and Bloodbank and Department of Immunology, Institute for Experimental Medical Research, Ullevaal University Hospital, Oslo, Norway

Plasma concentrations of the granulocyte cell marker calprotectin were assessed during operation and 24 hours postoperatively in patients undergoing coronary artery bypass grafting with cardiopulmonary bypass, abdominal aneurysmectomy with implantation of an aortic graft, or thoracotomy without implantation of synthetic material. The concentration of calprotectin increased significantly ($p < 0.01$) in all three groups. Ten of the 30 patients in the group undergoing cardiopulmonary bypass received methylprednisolone at the start of the operation. No difference in calprotectin concentration was seen between the two subgroups ($p > 0.05$). Plasma concentration of calprotectin was shown to increase rapidly in patients undergoing cardiopulmonary bypass and

aneurysmectomy, in whom complement activation also took place. However, the calprotectin concentration increased slowly during the operation and the postoperative period in patients undergoing a thoracotomy, in whom complement was not activated. At wound closure the calprotectin concentration was significantly elevated in the cardiopulmonary bypass and aneurysmectomy groups compared with the thoracotomy group ($p < 0.05$). The calprotectin concentration remained elevated during the postoperative period in all three groups. Our results indicate that calprotectin may serve as a suitable cellular marker when the biocompatibility of artificial surfaces is studied.

(*Ann Thorac Surg* 1993;55:694-9)

Complement activation occurs when blood is exposed to artificial material during extracorporeal circulation as in cardiopulmonary bypass (CPB) and hemodialysis [1]. Activation of the complement system leads to the generation of many biologically active fragments. The potent anaphylatoxin C5a may cause activation and accumulation of polymorphonuclear neutrophils (PMNs).

A transient leukopenia occurs during CPB and hemodialysis as a result of PMNs being removed from the circulation and sequestered in the lungs [2, 3]. This phenomenon is suggested to be caused mainly by the generation of C5a [4].

The calprotectin (L1) molecule is a major neutrophil cytoplasmic protein and is found both in squamous epithelial cells and monocytes but is absent in lymphocytes [5, 6]. Although its function *in vivo* is presently unknown, it has recently been shown that calprotectin has antibiotic properties and may be fungicidal and bactericidal *in vitro* [7].

Elevated plasma levels of calprotectin have been observed in patients with infections and various inflammatory diseases [8, 9]. Calprotectin is released from the cells upon activation and cell death and may thus be a useful marker of PMN activity [10, 11].

Recently calprotectin has been shown to be released during CPB [12]. In the present study the release of calprotectin during major operations with and without CPB was monitored and compared with the previously reported changes in complement activation occurring during these procedures [13, 14].

Patients and Methods

The study was performed on blood samples from patients previously described [13, 14]. Thirty patients (25 men and 5 women) underwent elective coronary artery bypass grafting. Seven patients (all men) underwent abdominal aneurysmectomy with implantation of an aortic woven Dacron graft, and 5 patients (3 men and 2 women) underwent a thoracotomy without implantation of synthetic material. In the coronary artery group 10 patients received methylprednisolone (30 mg/kg body weight) intravenously immediately before the start of CPB. The median age in the CPB group was 57 years (range, 35 to 68 years). The median age in the aneurysmectomy group was 68 years (range, 54 to 77 years), and in the thoracotomy group, 56 years (range, 41 to 69 years). The age difference among the groups was not statistically significant. No differences in operation time (169 minutes; range, 97 to 285 minutes) or duration of CPB (70 minutes; range, 29 to 128 minutes) were observed between the two CPB groups. Aortic cross-clamping was initiated in the

Accepted for publication June 26, 1992.

Fig 1. Plasma concentration of calprotectin in 20 patients undergoing coronary artery bypass grafting with cardiopulmonary bypass (CPB). Median values and interquartile range are shown.

aneurysmectomy group 75 minutes (range, 51 to 126 minutes) after the start of the operation. The median aortic cross-clamping time was 71 minutes (range, 49 to 115 minutes).

Anesthesia was performed according to a standard procedure including thiopental sodium, diazepam, fentanyl, pancuronium, and nitrous oxide.

For CPB a polystan VT 11500 bubble oxygenator connected to a 2,000-mL cardiectomy reservoir (Polystan, Copenhagen, Denmark) and an HF-6000 Swank arterial filter (Pioneer Viggo Inc, Beaverton, OR) were used in all patients. The extracorporeal circuit was primed with 500 mL of dextran in sodium chloride (0.9%), 500 mL of Ringer's acetate, 500 mL of glucose (5%), 500 mL of mannitol (15%), and 250 mL of carbonic acid (4.2%) (500 mmol/L).

Blood samples were drawn from the left radial artery before anesthesia and at the start of the operation. In the CPB group blood samples were drawn when CPB was established and then 30 minutes and 60 minutes after the start of CPB. In the other groups corresponding samples were obtained 1 hour after the start of the operation and 30 and 60 minutes later. In all patients additional samples were drawn at wound closure and every 4 hours for 24 hours.

Blood samples were collected into tubes containing ethylenediaminetetraacetic acid and immediately stored on ice. The samples were centrifuged within the next 3 hours, and the plasma was stored at -70°C until testing.

In each sample the number of white blood cells and the hemoglobin concentration were determined in an electronic counter (Coulter Electronics Ltd, Harkenden, UK). Blood smears were stained with May-Grünwald Giemsa stain and incubated with α -naphthyl acetate for demonstration of nonspecific esterase activity.

Plasma calprotectin level was determined by a double antibody enzyme immunoassay [15]. In brief, polystyrene plates were coated with a polyclonal rabbit anti-

calprotectin antibody. Standards and samples were incubated at room temperature. The second antibody was a polyclonal rat anti-calprotectin antibody. The detection antibody was alkaline phosphatase conjugated rabbit anti-rat immunoglobulin. *P*-nitrophenyl phosphate was used as substrate. Within assay precision was calculated to be 1.9% and between assay precision 14.8%. Lower detection limit was found to be $1.0\ \mu\text{g/L}$. The normal plasma level for calprotectin is 0.08 to 0.80 mg/L for women and 0.15 to 0.91 mg/L for men.

The PMN counts and plasma C3dg and plasma terminal complement complex (TCC) concentrations have previously been reported [13, 14].

Cell counts and concentrations of complement activation products and calprotectin were corrected for hemodilution according to the formula:

$$\frac{\text{Sample concentration} \times \text{initial hemoglobin}}{\text{Sample hemoglobin}}$$

All data are given as median values with interquartile range. The Friedman test was applied for comparison of samples drawn at different times within each group. Values were compared with baseline. The Kruskal-Wallis test was used for comparisons between the various groups and was examined at wound closure and 24 hours postoperatively. Values of *p* less than 0.05 were considered significant (two-tailed test).

The study was approved by the ethical committee of Ullevaal Hospital, and informed consent was obtained from each patient.

Results

Plasma Calprotectin

During CPB in the nonsteroid subgroup the calprotectin concentration increased from a baseline value of 0.5 mg/L (range, 0.5 to 0.9 mg/L) to a maximum of 11 mg/L (range,

Fig 2. Plasma concentration of calprotectin in 10 patients undergoing coronary artery bypass grafting and given methylprednisolone (30 mg/kg body weight) immediately before cardiopulmonary bypass (CPB). Median values and interquartile range are shown.

7.3 to 14.5 mg/L) 4 hours postoperatively ($p < 0.01$) (Fig 1). In the steroid subgroup the calprotectin concentration likewise reached a peak of 9.6 mg/L (range, 3.8 to 10.1 mg/L) 4 hours after the operation ($p < 0.01$) (Fig 2). After the initial peak the concentration of calprotectin gradually decreased to 4.5 mg/L (range, 3.3 to 6.6 mg/L) in the nonsteroid subgroup and to 5.6 mg/L (range, 3.8 to 5.9 mg/L) in the steroid subgroup 24 hours after the operation. However, the concentration remained markedly elevated compared with baseline ($p < 0.01$). The two subgroups did not differ significantly with regard to concentration of calprotectin in plasma ($p > 0.05$).

In the aneurysmectomy group the calprotectin concentration was 0.7 mg/L (range, 0.4 to 1.4 mg/L) before the operation. An increase in calprotectin concentration was seen after aortic cross-clamping was initiated and contin-

ued to rise after release of the clamp to 8.5 mg/L (range, 6.7 to 15.6 mg/L) at wound closure ($p < 0.02$). Then the calprotectin concentration gradually decreased to 6.7 mg/L (range, 4.1 to 9.4 mg/L) 24 hours after the operation (Fig 3). The concentration remained markedly elevated, however, compared with baseline ($p < 0.01$).

In the thoracotomy group the calprotectin concentration increased from 0.6 mg/L (range, 0.4 to 1 mg/L) before the operation to 6.1 mg/L (range, 3.8 to 10.2 mg/L) 8 hours after the operation ($p < 0.05$) (Fig 4). The calprotectin concentration remained elevated during the rest of the study period.

At wound closure the concentration of calprotectin was significantly elevated in the CPB and aneurysmectomy groups compared with the thoracotomy group ($p < 0.05$). Twenty-four hours after the operation no significant dif-

ference in calprotectin concentration was found between the groups ($p > 0.05$).

Plasma C3dg

As previously reported [13, 14], during CPB in the non-steroid subgroup (Fig 5) and in the steroid subgroup (data not shown) the C3dg concentration reached a peak value 4 hours after the operation and at wound closure, respectively, and then gradually decreased toward baseline during the observation period. The two subgroups did not differ significantly in regard to concentration of C3dg in plasma. In the aneurysmectomy group the changes in C3dg concentration were almost identical to observations in the CPB group (Fig 6). In the thoracotomy group the C3dg concentration remained unchanged during the observation period (Fig 7).

Plasma Terminal Complement Complex

As previously reported [13, 14], during CPB in the non-steroid subgroup (see Fig 5) and the steroid subgroup

(data not shown) the TCC concentration reached a peak value after 1 hour. Four hours postoperatively the TCC concentration had decreased almost to baseline. In the aneurysmectomy and thoracotomy groups no changes in TCC concentrations were observed (see Figs 6, 7).

Polymorphonuclear Neutrophils

As previously reported [13, 14], after 30 minutes of CPB there was a significant decrease in PMN count in both the nonsteroid subgroup (see Fig 5) and the steroid subgroup (data not shown), with no significant intergroup difference. However, in the postoperative period a significant difference was observed. In the nonsteroid subgroup a maximum was reached 8 hours after the operation, whereas in the steroid group the PMN count gradually increased during the observation period. At 12 hours and throughout the study the PMN count was significantly higher in the steroid subgroup than in the nonsteroid subgroup. In the aneurysmectomy group the number of PMNs increased steadily after the start of the operation,

reaching a peak 12 hours postoperatively (see Fig 6). The number of PMNs remained elevated during the observation period. In the thoracotomy group a gradual increase in PMNs was observed after the start of the operation to a maximum at 24 hours postoperatively (see Fig 7).

Comment

This investigation shows that calprotectin is released from PMNs during major operations with or without extracorporeal circulation. The release of calprotectin at the start of CPB coincided with the increase in C3dg and TCC levels and the transient decrease in PMN count. In the aneurysmectomy group the increase in calprotectin level corresponded with the increase in C3dg level that was seen when aortic cross-clamping was initiated. Aortic cross-clamping has previously been shown to induce complement activation [16]. After unclamping, when the blood came in contact with the implanted aortic Dacron graft the concentration of calprotectin and C3dg continued to increase. At wound closure we observed that the calprotectin concentration was significantly elevated in the CPB and the aneurysmectomy groups compared with the thoracotomy group. However, postoperatively no difference in the calprotectin concentration was observed. This implies that blood contact with artificial surfaces may

induce release of calprotectin. The actual release of calprotectin may have been underestimated during coronary artery bypass grafting because the CPB circuit itself may adsorb circulating proteins [17]. Our results suggest that calprotectin is a suitable marker for leukocyte activation when blood is exposed to synthetic materials. More conclusive information, however, may be obtained from the in vitro biocompatibility model developed by Videm and associates [18, 19].

C3dg and TCC are recognized as appropriate indicators of complement activation. This is in contrast to measurement of C5a due to the short plasma half-life of this molecule [13]. Because C5a is known to induce PMN aggregation, sequestration, and activation [20], it is tempting to speculate that the initial release of calprotectin during CPB and aneurysmectomy is caused by complement activation. In vitro studies have shown that binding of C5a to PMNs provokes the cells to release the content of the primary and secondary granules [21]. Moreover, the hypothesis that release of PMN granular contents in vivo is complement-dependent is supported by studies that have shown increased plasma levels of elastase and lactoferrin during hemodialysis [22, 23].

In both the CPB and the aneurysmectomy groups the C3dg concentration returned almost to baseline after the operation. In contrast, the calprotectin concentration re-

Fig 7. Plasma concentration of C3dg, terminal complement complex (TCC) and polymorphonuclear neutrophils (PMN) in patients undergoing thoracotomy. (Reprinted from Fosse E, Mollnes TE, Ingvaldsen B. *J Thorac Cardiovasc Surg* 1987;93:860-6, with permission.)

mained elevated in the postoperative period. This may partially be due to the previously described elevation of calprotectin level seen during inflammation and tissue repair [8, 9]. Our observations from the thoracotomy group support this view because the calprotectin concentration increased slowly during the postoperative period even if no complement activation was observed. Thus, additional mediators besides complement may induce calprotectin release.

Administration of methylprednisolone before CPB affected neither the generation of calprotectin nor the generation of complement activation products. This is an interesting observation because the PMN count increased significantly more in the steroid group than in the non-steroid group. Moreover, treatment with corticosteroids is known to modulate PMN responses in general [20, 24].

The clinical significance of calprotectin measurements is still obscure. However, the recent findings that calprotectin has a significant antibacterial effect and is released in response to endotoxins indicate that the molecule may have important in vivo functions [7, 10].

In conclusion, our results show that the initial release of calprotectin seen during CPB and aneurysmectomy coincided with the activation of the complement system. The antimicrobial effect of calprotectin and its presence in PMNs and macrophages may further link the complement system to cellular host defense mechanisms. Moreover, calprotectin may serve as an appropriate cellular indicator when the biocompatibility of artificial surfaces is studied.

Effects of Pressure and Duration of Hyperkalemic Infusions on Endothelial Function

Raymond Cartier, MD, Michel Pellerin, MD, Charleen Hollmann, RN, and L. Conrad Pelletier, MD

Department of Cardiovascular Surgery, Montreal Heart Institute, Montreal, Quebec, Canada

Infusions of crystalloid hyperkalemic cardioplegic solutions (CHCSs) are known to impair endothelium-dependent coronary relaxation. This impairment might also be influenced by high perfusion pressure and duration of CHCS infusion. To verify this hypothesis, we designed experiments to study the influence of pressure and duration of CHCS infusion as modulating factors in CHCS-related endothelial impairment. Isolated hearts of Sprague-Dawley rats were studied in a Langendorff apparatus for coronary endothelial function. Hearts ($n = 6$) were exposed to four different CHCSs containing 12, 24, 40, or 100 mmol/L of potassium chloride (KCl). Endothelial and smooth muscle functions were respectively tested by infusion of 5-hydroxytryptamine (1×10^{-6} mol/L) and sodium nitroprusside (1×10^{-5} mol/L) before and after CHCS perfusion. In group I ($n = 24$),

37°C CHCSs were perfused at 80 cm H₂O of pressure for 30 minutes. In group II ($n = 24$), the same CHCSs were perfused at 160 cm H₂O for 30 minutes. In group III ($n = 18$), CHCSs containing 24, 40, and 100 mmol/L of KCl were infused at 160 cm H₂O for 10 minutes. In all groups, response to sodium nitroprusside was unaltered by CHCS infusion, indicating that smooth muscle function was preserved. However, in group II, 5-hydroxytryptamine-induced vasodilatation was significantly impaired in hearts perfused with CHCS containing 24 mmol/L of KCl or more, suggesting endothelial damage. This study demonstrates that, in addition to KCl concentration, pressure and duration of infusion are two major determinants in CHCS-mediated endothelial damage.

(*Ann Thorac Surg* 1993;55:700-5)

Crystalloid hyperkalemic cardioplegic solutions (CHCSs) are currently used to optimize myocardial protection during open heart operations [1, 2]. The principle common to all these solutions is the rapid induction of diastolic myocardial arrest due to their high potassium content. Although hyperkalemia itself has not been reported to be harmful to myocytes, it has been suggested that it might affect the vascular endothelium. Potassium has been used to induce endothelial denudation in vessels [3]. Other authors [4-6] have demonstrated that crystalloid cardioplegic solutions could alter the cellular morphology and the survival of cultured endothelial cells.

Previous studies have shown that 5-hydroxytryptamine (5-HT) causes an endothelium-dependent increase in coronary flow in the isolated perfused rat heart through the release of nitric oxide [7-9]. Nitric oxide is known as an endothelium-derived relaxing factor and thus may play a major role in vasoregulation and hemostasis. It inhibits platelet adhesion and aggregation and is also a powerful smooth muscle relaxant [10-13]. Besides endothelium-derived relaxing factor, the vascular endothelium produces prostacyclin, antithrombin III, and plasminogen activator, all of which prevent platelet aggregation and promote vasodilatation. Therefore, endothelial functional disturbances can cause flow impairment and might play a

role in the reperfusion syndrome after bypass operations [14-16].

Recently, it has been reported that crystalloid hyperkalemic cardioplegic perfusion could impair 5-HT endothelium-dependent coronary relaxation in the isolated Langendorff-perfused rat heart [17, 18]. Although potassium concentration was shown to be related to endothelial damage, these studies did not exclude other physical factors, such as CHCS infusion pressure and time exposure to CHCS. In the present study, the isolated, perfused rat heart model was used to investigate the effects of CHCS potassium concentration combined with infusion pressure and duration of CHCS exposure on endothelium-dependent coronary artery relaxation.

Material and Methods

Animal Preparation and Reagents

Hearts were obtained from male Sprague-Dawley rats (body weight, 250 to 300 g) maintained on a standard laboratory diet. 5-Hydroxytryptamine and sodium nitroprusside (SNP) were obtained from Sigma Chemicals Ltd, St. Louis, MO. Crystalloid hyperkalemic cardioplegia solution was made of standard lactated Ringer's solution to which KCl was added. All animals were cared for in compliance with the "Guide for the Care and Use of Laboratory Animals" published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Accepted for publication June 30, 1992.

Address reprint requests to Dr Cartier, Montreal Heart Institute, 5000 Belanger St East, Montreal, Que HIT 1C8, Canada.

Perfusion Technique

The rats were heparinized (3 mg/kg) and decapitated. The chest was immediately opened, and the aorta was isolated, cannulated, and perfused in vivo with 37°C oxygenated (95% O₂, 5% CO₂) Krebs-Ringer solution containing (in millimoles per liter): NaCl, 118.3; KCl, 4.7; MgSO₄, 1.2; KH₂PO₄, 1.22; CaCl₂, 1.3; NaHCO₃, 25.0; and glucose, 15; pH 7.4 at 37°C. The perfused hearts were excised from the chest and mounted onto a modified Langendorff apparatus [19]. Using this harvesting technique, myocardial ischemia was kept at less than 45 seconds. The perfusion pressure was maintained at 80 cm H₂O. The hearts were atrially paced at 300 to 350 beats per minute. The maximal left ventricular pressure and its first time derivative (dP/dt) were measured by inserting a latex balloon inside the left ventricle through the left atrium and inflating it to maintain a left ventricular end-diastolic pressure of 10 mm Hg. Left ventricular pressure was measured with a Gould transducer signal conditioner (Gould 20-4615-50, Cleveland, OH), and dP/dt was recorded using a Gould differentiator signal conditioner (Gould 13-G4615-71). The mean and pulsatile coronary flow were measured using a 2-mm factory-precalibrated cannulating ultrasonic probe (Transonic cannulating flow probe, type 2N; internal diameter, 3.2 mm; resolution, 0.1 mL/min; Transonic System Inc, Ithaca, NY) to which the aorta was attached. Two hearts were studied simultaneously in two Langendorff apparatuses and all data recorded in a eight-channel Gould recorder.

Drugs were dissolved in Krebs-Ringer solution and perfused with a Harvard syringe infusion pump 22 (Harvard Apparatus, South Natick, MA) to assure a constant drug delivery (5-HT, 1×10^{-6} mol/L; SNP, 1×10^{-5} mol/L) during coronary perfusion.

Protocol

After harvesting, hearts were perfused and stabilized for a period of 30 minutes in the Langendorff apparatus. At the end of this period, the coronary basal flow, left ventricular dP/dt, and left ventricular pressure were recorded for baseline values. Then 5-HT and SNP were sequentially infused into the rat aorta, through the cannula, for a period of 4 minutes each. Changes in coronary flow were recorded at the end of the 4-minute infusion. Each drug infusion was followed by a 30-minute washout period, to allow the coronary flow to return to control values. The drugs were always administered in the same sequence, 5-HT first followed by the SNP, 30 minutes later. After these steps, hearts were exposed to different cardioplegic solution perfusions as further described in the "Experimental Groups" section. This was followed by a 30-minute recovering period in which hearts were reperfused with 37°C Krebs-Ringer solution at 80 cm H₂O of perfusion pressure. Basal coronary flow, left ventricular dP/dt, and left ventricular pressure were recorded at the end of the recovering period. Hearts were then resubmitted to 5-HT and SNP infusion, and coronary flow changes were recorded as previously described.

Experimental Groups

In group I (n = 24), four subsets (n = 6) of isolated hearts were perfused with different potassium concentration solutions (12 mmol/L, 24 mmol/L, 40 mmol/L, and 100 mmol/L) at 80 cm H₂O of pressure and for a period of 30 minutes. In group II (n = 24), four subsets (n = 6) were exposed to the same potassium concentrations but the perfusion pressure was increased to 160 cm H₂O for a 30-minute exposure. In group III (n = 18), three subsets of hearts (n = 6) were exposed to CHCS containing 24 mmol/L, 40 mmol/L, and 100 mmol/L of KCl and the perfusion pressure was maintained at 160 cm H₂O but for a period of 10 minutes.

Data Analysis

Changes in coronary flow are reported as a percentage of the baseline value. Baseline flow is recorded in milliliters per minute. For statistical purposes, because the baseline flow was not necessarily the same throughout the experiment, differences in flow change before and after exposure to cardioplegia in the same group are reported as percent change and not mean change of the raw values. All data are expressed as the mean $\pm$ standard deviation. Statistical analysis was performed by Student's paired *t* test. The statistical significance of differences was established at 95% (*p* < 0.05).

Results

Group I (perfusion pressure, 80 cm H₂O; duration, 30 minutes)

Before CHCS perfusion both 5-HT and SNP caused a significant increase in coronary flow in all hearts. Coronary flow, with both drugs, did not change significantly after CHCS perfusion at all KCl concentrations, indicating that muscle tone and endothelial reactivity were still present (Fig 1).

Group II (perfusion pressure, 160 cm H₂O; duration, 30 minutes)

In this group, with the perfusion pressure doubled, the increase in coronary flow caused by SNP remained unaffected at all potassium concentrations. However, the 5-HT vasodilatory effect was severely decreased (*p* < 0.01) at KCl concentrations of 24 mmol/L or more (Fig 2). At a KCl concentration of 100 mmol/L, the endothelial response was virtually abolished (mean flow increase before infusion, 40% $\pm$ 10%; after infusion, 2% $\pm$ 18%; *p* < 0.01).

Group III (perfusion pressure, 160 cm H₂O; duration, 10 minutes)

When the same high perfusion pressure was used but the duration of perfusion was decreased to 10 minutes, the increase in coronary flow induced by 5-HT and SNP infusion did not change significantly by CHCS infusion at any potassium concentrations (Fig 3).

Ventricular Function

Left ventricular pressure and dP/dt remained unchanged after CHCS infusion in all these experiments, indicating

Fig 1. Percentage increase in coronary flow induced by (A) 5-hydroxytryptamine (10^{-6} mmol/L) and (B) sodium nitroprusside (10^{-5} mmol/L) before (open bars) and after (solid bars) a 30-minute infusion at a pressure of 80 cm H₂O of hyperkalemic cardioplegic solutions containing 12, 24, 40, and 100 mmol/L of KCl.

that the hearts were functionally unaffected throughout the study (Table 1).

Baseline Flow

Baseline coronary flow decreased significantly after CHCS exposure in all groups (Table 2). One group failed to record a significant decrease in baseline flow (first subset of group III: 160 cm H₂O of perfusion pressure, 10-minute perfusion time, 24 mmol KCl/L), and this could be related to a larger variability in this group (9.3 ± 0.9 mL/min versus 8.15 ± 2.7 mL/min; p = not significant).

Comment

Nitric oxide release is one of the major functional aspects of the vascular endothelium. Nitric oxide inhibits platelet adhesion and aggregation, and is also a powerful vasodilator [10-13]. Serotonin has been shown to promote nitric

oxide release in rat coronaries [7, 8]. In the present study, the combined effect of KCl concentration, perfusion pressure, and duration of exposure was analyzed. The results indicate that in the rat, a perfusion of 30 minutes with crystalloid cardioplegic solution containing up to 100 mmol/L of KCl had no effect on 5-HT endothelium-dependent coronary vasodilatation when a perfusion pressure of 80 cm H₂O was used. Increasing the perfusion pressure to 160 cm H₂O severely decreased the coronary endothelial vasodilator response to 5-HT in hearts exposed to CHCS containing 24 mmol/L or more of KCl. Decreasing the duration of exposure to CHCS neutralized the detrimental effect of high infusion pressure and provided protection of the endothelial function even at very high potassium concentrations (100 mmol/L). Sodium nitroprusside-induced coronary vasodilatation remained unaffected at all KCl concentrations, perfusion pressures, and duration of exposures studied, indicating that the

Fig 2. Percentage increase in coronary flow induced by (A) 5-hydroxytryptamine (10^{-6} mmol/L) and (B) sodium nitroprusside (10^{-5} mmol/L) before (open bars) and after (solid bars) a 30-minute infusion at a pressure of 160 cm H₂O of hyperkalemic cardioplegic solutions containing 12, 24, 40, and 100 mmol/L of KCl. The difference in response to 5-hydroxytryptamine is significant ($p < 0.01$), whereas the response to sodium nitroprusside remained similar.

Fig 3. Percentage increase in coronary flow induced by (A) 5-hydroxytryptamine (10^{-6} mmol/L) and (B) sodium nitroprusside (10^{-5} mmol/L) before (open bars) and after (solid bars) a 10-minute infusion at a pressure of 160 cm H₂O of hyperkalemic cardioplegic solutions containing 24, 40, and 100 mmol/L of KCl.

smooth muscle reactivity was not altered by the various perfusion conditions. Similarly, left ventricular pressure and dP/dt were not significantly affected, suggesting little ischemic damage to the myocardium during the experiments. Therefore, it is conceivable that the endothelium was protected from ischemic damage. However, basal flow was constantly diminished after CHCS infusion. Perfusion pressures of 80 and 160 cm H₂O were selected

because they explore the whole spectrum of the normal blood pressure in the rat (diastole, 60 to 90 mm Hg; systole, 110 to 130 mm Hg) [20] and they represent the perfusion pressure that rat coronary arteries are normally exposed to.

Evidence of CHCS-induced endothelial injury has been previously reported. In regard to endothelial cell survival, Carpentier and co-workers [4] studied the cytotoxicity of 12 different cardioplegic solutions using the tissue culture technique. A cell death rate of 4.2% to 13.1% was found after 3 hours of incubation (10°C) with all cardioplegic solutions. However, the role of hyperkalemia per se was not specifically evaluated. Von Oppel and associates [21], using the same model, performed a similar study on

solid-organ preservation solutions and endothelial cell toxicity. Different intracellular and extracellular types of preservation solutions were studied and no detrimental effect on cell survival related to high potassium concentrations (up to 115 mmol/L), as in the Collins solution, could be demonstrated. As for structural defects, Solberg and colleagues [5, 22] described morphological damage at scanning and transmission electron microscopy when cultured endothelial cells were incubated with either the St. Thomas or the Bretschneider solution (containing, respectively, 20 and 10 mmol/L of KCl), but these changes were only transient and reversed almost completely after rewarming in the culture medium for 35 minutes. Follette and associates [6] and Harjula and colleagues [23] have shown a loss of endothelium and an increase in platelet deposition in coronary arteries submitted to hyperkalemic (20 mmol/L of KCl; perfusion pressure, 80 mm Hg) crystalloid cardioplegic solution.

Besides causing morphological changes to the endothelium, CHCS can also damage endothelial secretory function. Saldanha and Hearse [17] and Mankad and associates [18] reported deleterious effects of hyperkalemic CHCS on 5-HT-induced endothelium-dependent coronary vasodilatation. Their study showed a severe decrease in endothelium-dependent vasodilatation after exposure to St. Thomas or Bretschneider solutions containing 25 mmol/L or more of KCl. In both experiments, CHCS perfusion pressure was maintained at 100 cm H₂O for a period of 30 minutes or more. Compared with our results, more endothelial damage was obtained by these authors at lower KCl concentrations. This may be due to the higher perfusion pressure (100 instead of 80 cm H₂O) and to the different cardioplegic solutions used in their experiments. The effect of MgCl (present at a concentration of 16 mmol/L in the St. Thomas solution) on the vascular endothelium is not known. Bretschneider solution contains 7.3 mmol/L of procaine hydrochloride, which has been reported to increase cytotoxicity of CHCS on cultured endothelial cells [5]; it could therefore potentially affect endothelium-derived relaxing factor release by the endothelium.

The purpose of the present study was to examine the effect of different KCl concentrations combined with mechanical and time factors on endothelial function. Lactated Ringer's solution, with KCl the only added component, was chosen to minimize chemical interactions. One possible flaw of our study is that the osmolarity was not corrected when a high KCl concentration was added. However, significant damage was obtained with CHCS containing 24 mmol/L of KCl, whereas the osmolarity of the solution is 313 osm/L, which is still in a normal range. Therefore, high osmolarity cannot be the only responsible factor for endothelial dysfunction.

Basal coronary flow was constantly decreased after CHCS perfusion, suggesting a decrease in the basal endothelium-derived relaxing factor release by the resting endothelium. However, other contributing factors such as a decrease in prostacyclin production or myocardial swelling and stiffness as the experience goes on could contribute to this drop in basal coronary flow [24]. Any endothe-

lial alteration may be the cause of platelet aggregation and vasospasm due to the release of vasoactive compounds, causing the unprotected smooth muscle to contract and as a result contribute to poor myocardial performance in clinical situations [15].

Because the 5-HT-induced coronary relaxation was preserved, it can be inferred that the coronary vessels were still protected against platelet aggregation and thrombus formation by normal release of endothelium-derived relaxing factor.

Our results indicate that it is possible to perfuse high potassium concentrations with minimal endothelial dysfunction, provided that pressure and duration of exposure are also considered. A high KCl concentration appears to be well tolerated at a low perfusion pressure and for a short period of exposure. This indicates that KCl concentration is not the only damaging factor and other physical factors must also be considered to avoid functional damage to the endothelium during CHCS perfusion. This finding may be of clinical significance in myocardial protection during cardiac operations.

Paranasal Sinusitis: Cryptic Sepsis After Coronary Artery Bypass Operations

Anthony L. Picone, MD, Clinton E. Baisden, MD, Edward G. Ford, MD, and Mark E. Sand, MD

Division of Thoracic Surgery, Department of Surgery, Keesler Medical Center (ATC), Keesler Air Force Base, Mississippi

Infections occurred in 52 of 400 patients (13%) undergoing coronary artery bypass operations from January 1987 to December 1990. The hospital courses of 5 patients (1.3%) in whom occult infections of the paranasal sinuses developed were reviewed. Only 1 patient had specific clinical findings of acute sinusitis (purulent nasal discharge). Computed tomography showed wall thickening, opacification, or air-fluid levels in one or more paranasal sinuses in each patient. All patients were successfully treated with surgical drainage and antibiotics. Risk fac-

tors for development of postoperative acute sinusitis include: prolonged tracheal intubation, airway colonization with nosocomial bacteria, inability to clear nasal secretions, sinus ostial obstruction, and critical organ system dysfunction. Physical examination and roentgenographic evaluation of the paranasal sinuses should be considered when postoperative sepsis of obscure etiology occurs.

(*Ann Thorac Surg* 1993;55:706-10)

Infections are a source of major morbidity and mortality after cardiac operations. Sepsis may be the result of pneumonia, mediastinitis, urinary tract infections, endocarditis, or infected prosthetic materials [1, 2]. When inadequately treated, sepsis results in multisystem organ failure and death.

In 1985 one of us (C.E.B.) performed a coronary artery bypass operation (CAB) on a patient in whom postoperative sepsis and multisystem organ failure developed. An exhaustive search for a septic source was unsuccessful. The patient died despite administration of broad-spectrum antibiotics and intensive supportive care. Autopsy revealed suppurative maxillary sinusitis as the probable site of sepsis. We present 5 similar patients and discuss their clinical course and management.

Material and Methods

Methods

We retrospectively reviewed the records of 400 consecutive patients undergoing CAB from January 1987 to December 1990. In 52 patients (13%) postoperative infections developed based on clinical and laboratory data or on pathologic tissue examination. These cases included wound infection (20), pneumonia (19), urinary tract infection (6), postoperative acute sinusitis (PAS) (5), mediastinitis (4), catheter sepsis (2), occult bacteremia (2), molar abscess (1), and acalculous cholecystitis (1).

The 5 patients in whom PAS developed (4 male, 1 female) were 53 to 73 years old (mean 63.4 years). The

diagnosis in all patients was based on (1) an abnormal computed tomographic scan of the paranasal sinuses defined as wall thickening, cavity opacification, or presence of air-fluid levels and (2) the finding of pus at the time of sinus aspiration or surgical drainage.

All patients undergoing CAB routinely received perioperative antibiotic prophylaxis consisting of 1 g of cefadyl intravenously at the time of induction and then every 6 hours for 48 hours. All patients had primary intraoperative orotracheal intubation. After routine extubation, 17 patients required reintubation (14 oral and 3 nasal). None of the patients in whom PAS developed were nasally intubated. One patient (patient 1) had an unsuccessful attempt at nasotracheal intubation. The 5 patients with PAS were endotracheally intubated from 10 to 27 days (mean, 14.2 days) before a diagnosis of PAS (Table 1). The 395 CAB patients without PAS were intubated from 1 to 23 days (mean, 1.4 days).

Nasal or oral gastric sump tubes for decompression (16F or 18F) were routinely placed intraoperatively and removed after tracheal extubation. Patients with PAS had nasogastric drainage tubes in place from 1 to 12 days (mean, 8.6 days) before a diagnosis of PAS, whereas the 395 CAB patients without PAS had nasogastric drainage for 0 to 23 days (mean, 1.3 days). The side of the nasal intubation could only partially be determined from review of the patient records.

Culture-specific systemic antibiotics were administered in 4 patients with PAS (Table 2). Three patients (patients 1, 2, and 5) were already receiving broad-spectrum antibiotics to which the putative organism(s) were sensitive. In 1 patient (patient 4) empiric vancomycin administration had been discontinued 48 hours before sinus drainage but the course was resumed upon obtaining productive bacterial cultures from the sinus drainage. One patient (pa-

Table 1. Endotracheal and Gastric Tubes in Patients With Postoperative Acute Sinusitis

Patient No.	Endotracheal Intubation (days)	Gastric Intubation (days)
1	13 (O) ^{a,b}	11 GT (N) (8 via right nares)
2	10 (O)	10 GT (N)
3	11 (O)	9 GT (N) (7 via left nares) 1 GT (O) 1 FT (N)
4	10 (O)	1 GT (N) (1 via left nares) 3 GT (O) 5 FT (N) (5 via left nares)
5	27 (O)	12 GT (N) 15 FT (N)

^a Successive intubations of 1, 2, and 10 days' duration. ^b Attempted nasal tracheal intubation at second reintubation.

FT = small-diameter feeding tube; GT = 16F to 18F gastric sump drainage tube; N = nasal; O = oral.

tient 3) in whom a definitive organism was not identified was treated with empiric clindamycin and ceftazidime.

One patient (patient 5) was treated unsuccessfully with topical phenylephrine hydrochloride (Neo-Synephrine; Winthrop Pharmaceuticals, New York, NY) and antibiotics for several days before surgical drainage. Aspiration and irrigation of an infected maxillary sinus was unsuccessful in eradicating a multiple sinus cavity infection in 1 patient (patient 1). Surgical pansinus endoscopic exploration and drainage of the infected sinuses was ultimately performed in all patients. Nasogastric drainage and feeding tubes were removed before exploration.

Each patient with PAS had preexisting organ system dysfunction (Table 3). All patients had pulmonary failure necessitating prolonged endotracheal intubation, 4 had renal failure (3 requiring dialysis), 3 had cardiac dysfunction (1 required a left ventricular assist device and an intraaortic balloon pump, 1 required an intraaortic balloon pump only, 1 required mediastinal reexploration for tam-

ponade) and 2 patients had central nervous system dysfunction (1 remaining comatose until death). Four patients had evidence of sepsis from sources in addition to the paranasal sinuses (respiratory tract, 4; tooth abscess, 1).

Case Presentations

PATIENT 1. Patient 1 is a 69-year-old man who underwent an urgent triple CAB. On postoperative day (POD) 3 a left *Enterobacter aerogenes* pneumonia developed. Multiple cultures of blood, sputum, urine, and intravascular catheters were negative. Due to persistent fever and leukocytosis on POD 9 the mediastinum was explored and found to be negative on Gram stain and bacterial culture. A subsequent sinus roentgenographic series was normal. The patient's mental acuity decreased but computed tomography of the brain and cerebrospinal fluid analysis were normal. The head computed tomogram did show opacification of the right maxillary sinus, and on POD 16, 1.5 mL of pus was aspirated from the sinus. Gram-negative rods and leukocytes were identified on fluid Gram stain. Cultures of the fluid grew *Proteus mirabilis*. Within 24 hours the patient's temperature decreased and the leukocyte (WBC) count returned to normal. Two days later the patient's fever recurred and the WBC count rose to $19.2 \times 10^9/L$ ($19,200/\mu L$). The left sphenoid sinus was surgically drained and the temperature and the WBC count rapidly normalized. The patient's respiratory and renal failure slowly improved.

PATIENT 2. Patient 2 is a 59-year-old man who underwent urgent sextuple CAB. A perioperative coagulopathy and cardiac tamponade developed, requiring three mediastinal explorations during the first 36 hours after CAB. On POD 2 adult respiratory distress syndrome and subsequent renal dysfunction developed. Multiple cultures of blood, sputum, urine, and intravascular catheters were negative. Sputum Gram stain showed WBCs with gram-positive cocci; a single sputum specimen grew *Candida albicans*. Computed tomography of the brain was normal but showed opacification of the ethmoid and sphenoid

ARDS = adult respiratory distress syndrome.

sinuses (Fig 1). The sinuses were surgically drained on POD 10. Cultures of fluid from the right ethmoid and left sphenoid sinuses grew *Staphylococcus epidermidis*. Within 48 hours the patient's temperature dropped to 38.3°C and the WBC count declined to $13.9 \times 10^9/L$ ($13,900/\mu L$). The patient's multisystem organ failure slowly resolved.

PATIENT 3. Patient 3 is a 53-year-old man who underwent emergent quadruple CAB. An intraaortic balloon pump and a left ventricular assist device were required to separate the patient from cardiopulmonary bypass. Adult respiratory distress syndrome developed, with subsequent *Escherichia coli* pneumonia and seizures. An abscessed lower molar tooth (*Staphylococcus coagulase negative*) was removed on POD 2, and by POD 3 all mechanical assist devices were removed. He demonstrated a septic course associated with progressive renal dysfunction. Due to purulent nasopharyngeal drainage a head computed tomogram was obtained, which showed a right maxillary sinus air-fluid level (Fig 2). On POD 11 he underwent surgical drainage and removal of purulent material from the right maxillary and sphenoid sinuses. Although no bacteria were isolated, the patient had immediate improvement of his clinical course.

PATIENT 4. Patient 4 is a 73-year-old man who underwent elective quintuple CAB. He suffered an intraoperative ventricular fibrillatory arrest and required both inotropic support and an intraaortic balloon pump. Consolidation of the left lower lung and adult respiratory distress syndrome developed. Multiple gram-negative bacteria and *Staphylococcus epidermidis* were cultured from the sputum. Renal dysfunction necessitated hemodialysis. A head computed tomogram to evaluate progressive alteration in mental status showed an air fluid level in the right maxillary sinus, which was then surgically drained on POD 10. *Staphylococcus epidermidis* was isolated from the sinus. After a brief period of improvement the patient again became septic. Acute acalculous cholecystitis was identified and surgically treated, but the patient eventually died of multisystem organ failure on POD 37.

PATIENT 5. Patient 5 is a 63-year-old woman with chronic obstructive pulmonary disease who underwent emer-

gency quadruple CAB. Pneumonia (probably gram positive) and adult respiratory distress syndrome developed on POD 3. Direct fiberoptic nasal examination revealed fluid in the maxillary sinuses. Treatment was begun with topical (Neo-Synephrine) and systemic antibiotics. She transiently improved, but then fever, leukocytosis, and culture-proven *Staphylococcus epidermidis* bacteremia developed. Head computed tomography showed opacification of all paranasal sinuses. All sinuses were surgically drained. Pus drained from the right maxillary sinus grew *Staphylococcus epidermidis*. Within 24 hours the patient's temperature and WBC count normalized. The patient's sepsis and multisystem organ failure resolved but she remained ventilator dependent. She died 4 months postoperatively after voluntary cessation of mechanical ventilation.

Results

Purulent nasopharyngeal drainage was observed in only 1 patient with PAS (patient 3). Patients with PAS were

Fig 1. (Patient 2.) Computed tomographic scan demonstrating partial opacification of the ethmoid sinus, greater on the right (arrow), and bilateral opacification of the sphenoid sinuses (arrowheads).

Fig 2. (Patient 3.) Computed tomographic scan demonstrating a right maxillary sinus air-fluid level (arrow).

febrile (38.7° to 39.8°C) and had leukocytosis (16 to 26.7 $\times 10^9/L$ [16,000/ μL to 26,700/ μL]). Other indicators of sepsis including tachycardia (120 to 125 beats/min), an inappropriately high cardiac index (3.0 to 4.4 $L \cdot min^{-1} \cdot m^{-2}$), systolic arterial hypotension (60 to 90 mm Hg), low systemic vascular resistance (600 to 740 dyne-s/cm⁵) and an increased catabolic rate (urinary urea nitrogen excretion of 26.4 to 30.3 g/24 h) were documented in 4 patients (Table 4).

Infected sinuses in patients with PAS included maxillary (4), sphenoid (3), and ethmoid (1); 3 patients (60%) had more than one infected paranasal sinus. Single organisms were cultured from the sinus drainage in 4 of the 5 patients with PAS (see Table 2). The tracheobronchial tree in all 5 patients was colonized by multiple organisms. In 1 patient (patient 1) *Proteus mirabilis* was cultured simultaneously from both the sinus and tracheobronchial tree. One patient (patient 5) had a documented bacteremia with the same organism isolated from the sinus drainage.

Two deaths occurred in the PAS group. One resulted from multisystem failure secondary to acalculous cholecystitis; the other occurred from respiratory failure after the patient and her family requested removal of long-term mechanical ventilation.

Comment

Acute sinusitis is reportedly responsible for 5% of all infection in trauma units and occurs in up to 25% of patients with central nervous system injury [3, 4]. Patients undergoing CAB previously have not been reported to be at serious risk for postoperative sinusitis. Cryptic sinus infections occurred in 1.3% of our CAB patients, which represents 9.6% of all of our postbypass infections. Postoperative acute sinusitis occurred only in patients who had a prolonged and complicated postoperative intensive care unit course.

Factors associated with occurrence of sinusitis in patients in the intensive care unit include maxillofacial

trauma, sedation, corticosteroids, and nasogastric catheterization [5-7]. However, nasotracheal intubation, especially if emergent or traumatic, is implicated as the leading cause of PAS [4, 8-12]. Bacteremia during nasal tracheal intubation and the direct obstruction of the paranasal sinus ostia by the characteristically large and stiff tube are thought by some to be etiologic [13]. Nasotracheal intubation was rarely performed in our patients. One patient underwent an attempted nasotracheal intubation, which resulted in a mucosal injury and possible sinus ostial occlusion.

Nasogastric tubes are also implicated in the development of PAS by causing mucosal irritation with subsequent sinus ostial obstruction [6, 8]. In our series, although nasogastric tubes remained in place on the average longer in patients with PAS than in those without PAS, in 3 patients infections occurred in sinus cavities contralateral to the nasogastric tube. This observation suggests that factors other than local obstruction may also be important.

Each patient had respiratory failure requiring prolonged oral tracheal intubation, and all patients had culture-documented colonization of the tracheobronchial tree. Although only 1 patient had an identical organism cultured simultaneously from tracheobronchial and sinus aspirates, the profile of bacteria cultured from the infected sinus could be anticipated as a result of usual nosocomial colonization. Broad-spectrum empiric antibiotics may have been incompletely effective and contributory to infection by selecting out resistant organisms. We would agree with others that opportunistic organisms responsible for PAS are dissimilar from the predominant *Streptococcus* and *Haemophilus* species occurring in outpatient sinusitis and that factors promoting colonization of the paranasal sinuses are important in the development of this disease [5-8, 11].

All patients with PAS had a prolonged period of immobility because of unconsciousness or administration of muscle relaxants to assist in mechanical ventilation. Our patients were similar in this way to those reported with central neurologic emergencies or trauma in whom PAS subsequently developed [5]. The inability of these patients to normally clear secretions may have promoted paranasal sinus colonization and ostial obstruction.

Table 4. Results in Patients With Postoperative Acute Sinusitis

Patient No.	Paranasal Sinus Cavities Infected	Complications	Outcome

^a See text for details. ^b Autopsy-proven acalculous cholecystitis and bile peritonitis. ^c Patient request for discontinuance of ventilatory support.

Critical illness and organ system dysfunction reflected as a mean APACHE II score of 20.36 has been correlated with development of PAS in trauma patients [6]. Although APACHE II scoring cannot be applied to patients after cardiac operations [14], our patients with PAS had serious perioperative complications resulting in major organ system dysfunction. Frequent nonsinus postoperative sepsis likely contributed to this process.

Diagnosis of acute sinusitis in unconscious critically ill patients is difficult because of the paucity of physical signs and symptoms [6, 8, 11]. Typically, the patient with PAS has sepsis of "cryptic" etiology as was seen in our series. Nonspecific signs such as fever and leukocytosis are often present; however, characteristic findings of PAS such as nasopharyngeal purulence are rare.

Previous reports suggest plain sinus roentgenograms, including a Water's view, are 90% accurate in diagnosing PAS. Sinus series radiographs obtained in 1 patient (patient 1) were not helpful. We found computed tomographic findings of PAS to be uniformly diagnostic. Moreover, involvement of the sphenoid or ethmoid sinuses (3 patients) is identified best by computed tomographic radiography [8, 11, 15, 16]. Hansen and associates [10] prospectively evaluated computed tomography of the paranasal sinuses in a group of 12 patients with central nervous system pathology who had undergone nasotracheal intubation. They found that 100% of the patients had radiographic evidence of PAS less than 3 days after intubation, and positive cultures from nasal purulent discharge eventually developed in 7 patients.

Several authors report good results with nonoperative measures including removal of nasal tubes, antibiotics, and topical decongestants [5, 7, 8, 10, 12, 17]. Twenty percent to 50% of patients in these reported series ultimately required therapeutic sinus aspiration and irrigations. In our series, treatment of PAS consisted of removal of all nasal tubes, administration of antibiotics, and surgical drainage. We are impressed with the rapid clinical improvement after surgical drainage.

Eighteen percent to 83% of patients with PAS are reported as having bacteremias [4, 6, 7, 17]. Only 1 patient in our series had a bacteremia. None of our patients had development of meningitis or brain abscess, which are reported sequelae of PAS [5, 7]. No deaths in our series were related to PAS. Again, our aggressive management of PAS may have minimized the morbidity.

We agree with reports that prevention of PAS centers around refraining from the use of large-diameter nasal tracheal tubes, which has been our practice. All nasogastric tubes (including feeding tubes) should be removed as early as possible or placed transorally. Frequent suctioning of nasopharyngeal secretions should help clear nasal airways and facilitate sinus drainage. We cannot substantiate whether prophylactic antibiotic therapy or topical decongestants will afford prophylaxis against occurrence of PAS. Routine preoperative nasal cultures are unlikely to forecast the profile of postoperative colonization of the nasopharynx. Such cultures would not aid in determining an appropriate antibiotic regimen.

Postoperative acute sinusitis is an uncommon complication after CAB operations. The infection typically occurs in patients with a protracted and complicated postoperative course. Patients requiring prolonged oral or nasal endotracheal intubation will have nosocomial colonization of the nasopharyngeal and tracheobronchial airways and will be at risk for PAS. Inability to clear nasal secretions may also predispose to development of PAS. Critically ill and physiologically stressed patients immunocompromised by augmented postoperative stress responses may be at particular risk. A high index of suspicion and well-planned radiographic diagnostic interventions are necessary to make the diagnosis of occult PAS. Surgical drainage is followed by immediate improvement and should be considered the treatment of choice.

Influence of Temperature of Flushing Solution on Lung Preservation

Liang-Shun Wang, MD, Kembu Nakamoto, MD, Chia-Ming Hsieh, MD, Shinichiro Miyoshi, MD, and Joel D. Cooper, MD

Division of Thoracic Surgery, Toronto General Hospital, and Department of Surgery, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada

For lung transplantation the technique of flushing the donor pulmonary vascular bed may provide advantages in lung preservation such as rapid cooling and washout of blood. However, rapid cooling of the ischemic lung may also produce adverse effects. The aim of this study was to compare methods of cold flushing and topical cooling, and to evaluate the effect of temperature of the flushing solution on lung preservation. A total of 25 rabbit lungs were studied. Using an ex vivo rabbit lung model, postischemic function was assessed by the ability of the lung to oxygenate perfused blood and by measurement of pulmonary artery and airway pressures. The lungs in group I were preserved with simple immersion at 10°C for 30 hours. The lungs in groups II through V were flushed with solution containing phosphate-

buffered dextran (LPD) at different temperatures (groups II and IV, 10°C; groups III and V, 23°C) and stored at 10°C for various ischemic periods (groups II and III, 30 hours; groups IV and V, 36 hours). Pulmonary vascular resistance during flushing at 10°C was significantly higher than that at 23°C ($p < 0.001$). Flushing resulted in better preservation than topical hypothermia. Flushing at 23°C resulted in superior postischemic function compared with flushing at 10°C. We conclude that in lung preservation, uniform flushing with LPD solution improves the ischemic tolerance as compared with topical hypothermia, and that flushing with solutions at too low temperatures may have adverse effects on lung preservation.

(*Ann Thorac Surg* 1993;55:711-5)

Flushing of the pulmonary vascular beds has been used in both experimental and clinical studies of lung preservation [1, 2]. Compared with preservation of the kidneys and liver, however, the results with flush preservation of the lung have been much less satisfactory.

Haverich and associates [2] reviewed the history of lung preservation and pointed out that many factors contributing to flush preservation have not yet been defined. One of these is the temperature of the flushing solution, which may be different from the optimum storage temperature.

Basically, the flushing technique in organ preservation can provide some advantages but may also be harmful. Flushing of the graft organs with solutions at low temperature may facilitate the rate of cooling but may also cause vasoconstriction with resulting incomplete perfusion of some areas of the lung, as well as cellular edema [3].

In this study, an ex vivo perfused rabbit model was used to compare the effects of cold flushing with topical cooling, and also to evaluate the influence of temperature of the flushing solution on lung preservation.

Material and Methods

Five groups ($n = 5$ for each group) of 3.2- to 3.5-kg white New Zealand rabbits' lungs were studied ex vivo using an

isolated perfused lung preparation, which was simplified from the previously described model [4]. The techniques of pulmonary artery cannulation and heart-lung block harvesting were similar to the previous model [4].

The rabbits were premedicated with subcutaneous atropine sulfate (0.25 mg/kg), ketamine (35 mg/kg), and acepromazine maleate (0.6 mg/kg). They were then anesthetized with intravenous sodium pentothal (25 mg/kg), and heparin (700 IU/kg) was administered into the ear vein. A cervical tracheostomy was rapidly performed and the trachea was intubated with a No. 3 endotracheal tube, which was then connected to a volume-cycled respirator (Harvard model 671). The lungs were ventilated with room air at a respiratory rate of 45 per minute, a tidal volume of 25 mL, and 0.5 cm H₂O of positive end-expiratory pressure.

The chest was opened by median sternotomy, and the superior vena cavae, ascending aorta, and pulmonary artery were mobilized and loosely encircled with ligatures. The pulmonary artery was cannulated with a 14F catheter through the right ventricular outflow tract for subsequent flushing of the lungs. This cannula was also used to measure mean pulmonary artery pressure (PAP). A drainage tube was placed into the left ventricle, and the animal was exsanguinated, which required less than 20 seconds. The pulmonary artery ligature was tied to secure the pulmonary artery cannula in place and the ascending aorta was ligated and divided. Immediately after this, in-site flushing was carried out while ventilation was continued. Using this technique, the warm ischemic pe-

Accepted for publication July 6, 1992.

riod was less than 90 seconds. Four hundred milliliters of flushing solution at the predetermined temperature was infused through the pulmonary artery cannula at a height of 60 cm; the effluent was drained through the left ventricular drainage tube. The tubing system for flushing consisted of a standard intravenous set tube of 70 cm, a stopcock (Cobe 11R 9703), and a 5-cm pulmonary artery cannula (Cobe 05P 9290). Duration and pulmonary artery pressure during flushing were recorded for calculating the pulmonary vascular resistance. As soon as the flushing was completed, the left ventricular drainage tube was removed with the ligation of the pursestring suture. Thus, the flushing solution was kept inside the heart-lung block, and isolated from the immersion solution during storage. The right PA and the right main bronchus were ligated after flushing. The average pulmonary vascular resistance (PVR) during flushing was calculated as follows: $PVR \text{ (mm Hg} \cdot \text{L}^{-1} \cdot \text{min)} = [\text{pulmonary artery pressure (mm Hg)} - \text{left atrial pressure (mm Hg)}] / \text{flow rate (L/min)}$. A modified phosphate-buffered extracellular (LPD) solution was used [5]. The composition of the solution was as follows: Na^+ , 168 mmol/L; K^+ , 4.0 mmol/L; chloride, 104 mmol/L; magnesium sulfate, 2.0 mmol/L; phosphate radical, 36.7 mmol/L; low-molecular-weight dextran, 2%; and heparin, 2,000 U/L.

In group I, the heart-lung blocks were harvested without flushing, inflated to tidal volume, and stored at 10°C for 30 hours. The ischemic period before immersion for cool storage in this group ranged from 10 to 15 minutes. For flush preservation (groups II through V), the lungs were flushed in-site at different temperatures (groups II and IV, 10°C; groups III and V, 23°C). They were then harvested, inflated to tidal volume, and stored at 10°C for various ischemic periods (groups II and III, 30 hours; groups IV and V, 36 hours).

For postischemic functional assessment, the left lung was ventilated with room air (rate, 25/min; tidal volume, 15 mL, positive end-expiratory pressure, 0.5 cm H_2O) and perfused with heparinized fresh rabbit venous blood (rate, 40 mL/min) for 10 minutes as previously described [4]. In the present model, unlike our previous report, a spirometer was not used in the ventilatory circuit. Thus oxygen uptake was not measured. The parameters for function assessment included gas analysis of venous perfusate and pulmonary venous effluent blood, $\overline{\text{PAP}}$, and mean airway pressure ($\overline{\text{P}_{\text{aw}}}$). Blood gases of the affluent blood were measured at 5 and 10 minutes; the other parameters were recorded continuously throughout the assessment.

All results were presented as mean $\pm$ standard error of mean. Statistical analysis was performed using the unpaired *t* test. Statistical significance was assumed for a *p* value less than 0.05.

All animals received humane care in compliance with the "Principles of Laboratory Care" formulated by the National Society for Medical Research, and the "Guide for the Care and Use of Laboratory Animals" prepared by National Academy of Sciences and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Fig 1. Flushing of lungs with LPD solution at 10°C resulted in a significantly higher pulmonary vascular resistance (PVR) compared with flushing at 23°C ($p < 0.001$).

Results

Venous Perfusate

The gas analysis and the hematocrits of pulmonary artery infusion blood did not differ among all groups. The oxygen tension was 16.5 ± 0.6 mm Hg; carbon dioxide tension, 65.5 ± 3.5 mm Hg; hemoglobin level, 105 ± 3 g/L; and hematocrit, 0.35 ± 0.03 ($n = 25$).

Mean Pulmonary Artery Pressure, Flow Rate, and Pulmonary Vascular Resistance During Flushing

Pulmonary artery pressure in the anesthetized rabbit before flushing was stable and constant (10.8 ± 0.3 mm Hg; $n = 20$). During flushing of the lungs at 23°C, the $\overline{\text{PAP}}$ was 10.7 ± 0.5 mm Hg; flow rate, 119.4 ± 2.0 mL/min; and PVR, 98.4 ± 5.0 mm Hg $\cdot \text{L}^{-1} \cdot \text{min}$ ($n = 10$). At a flushing temperature of 10°C, the $\overline{\text{PAP}}$ during flushing was 13.1 ± 0.5 mm Hg; flow rate, 91.9 ± 2.1 mL/min; and PVR, 144.9 ± 8.7 mm Hg $\cdot \text{L}^{-1} \cdot \text{min}$ ($n = 10$). During flushing at 23°C, the $\overline{\text{PAP}}$ was stable throughout the process, but the $\overline{\text{PAP}}$ at 10°C gradually increased during the initial 1 to 2 minutes of flushing and then became constant. Flushing of lungs at 10°C resulted in a significantly higher PVR compared with flushing at 23°C ($p < 0.001$) (Fig 1).

Table 1. Postischemic Functional Assessments^a

Group	Temperature of Flush Solution (°C)	Ischemic period (h)	PaO ₂ (mm Hg)		PaCO ₂ (mm Hg)		PAP (mm Hg)		P _{aw} (mm Hg)	
			5 min	10 min	5 min	10 min	5 min	10 min	5 min	10 min
I	No flushing	30	67.4 ± 12.5	65.3 ± 8.0	41.4 ± 3.6	39.8 ± 3.3	22.0 ± 2.8	21.4 ± 3.2	2.6 ± 0.9	2.6 ± 0.9
II	10	30	108.7 ± 5.2	95.3 ± 7.0 ^b	30.1 ± 0.8	30.8 ± 0.9 ^b	16.4 ± 0.7	16.4 ± 0.7	2.2 ± 0.1	2.2 ± 0.1
III	23	30	124.9 ± 1.4	120.0 ± 0.9 ^b	30.3 ± 0.6	30.7 ± 0.6	14.0 ± 0.7	13.6 ± 0.5 ^b	2.2 ± 0.1	2.2 ± 0.1

V	23	36	104.3 ± 9.1	105.2 ± 7.9 ^b	31.0 ± 0.6	30.5 ± 0.6	13.2 ± 0.6	12.7 ± 0.5 ^b	2.4 ± 0.3	2.7 ± 0.6

^a The lungs in group I (nonflushing group) were preserved only with simple cool (10°C) immersion. The lungs in groups II through V (flushing groups) were flushed in situ at different temperatures and then stored at 10°C for various ischemic periods. All data are presented as mean ± standard error of the mean. ^b $p < 0.05$ versus the group immediately above.

PaCO₂ = arterial carbon dioxide tension; PaO₂ = arterial oxygen tension; PAP = mean pulmonary artery pressure; P_{aw} = mean airway pressure.

Postischemic Pulmonary Functional Assessments

All data of pulmonary venous effluent blood oxygen tension (PaO₂), pulmonary venous effluent blood carbon dioxide tension (PaCO₂), PAP, and P_{aw} are presented in Table 1. The results of PaO₂ and PAP measurements are displayed graphically in Figures 2 and 3.

COMPARISON BETWEEN THE EFFECTS OF COLD FLUSHING AND TOPICAL HYPOTHERMIA. In comparison with the lungs with simple immersion at 10°C for 30 hours (group I), the lungs flushed at 10°C (group II) demonstrated significant improvement in PaO₂ (group I, 65.3 ± 8.0 mm Hg; group II, 95.3 ± 7.0 mm Hg at 10 minutes; $p < 0.05$) (see Fig 2) and PaCO₂ (group I, 39.8 ± 3.3 mm Hg; group II, 30.8 ± 0.9 mm Hg; $p < 0.05$). Higher values of PAP were also found in group I (see Fig 3), but the results obtained at 5 and 10 minutes were not significant compared with group

II ($0.1 < p < 0.05$). The P_{aw} in group I was similar to that in group II.

COMPARISON BETWEEN LUNGS FLUSHED AT DIFFERENT TEMPERATURES. At an ischemic period of 30 hours, for lungs flushed at 10°C (group II) the PaO₂ during perfusion was 95.3 ± 7.0 mm Hg, and PAP was 16.4 ± 0.7 mm Hg at 10 minutes. When the temperature of the flushing solution was 23°C (group III), there was a significant improvement in PaO₂ (120.0 ± 0.9 mm Hg at 10 minutes; $p < 0.05$) and a decrease in PAP (13.6 ± 0.5 mm Hg at 10 minutes; $p < 0.02$) compared with group II. There was no difference in PaCO₂ and P_{aw} between groups II and III.

When the ischemic period was prolonged to 36 hours, the PaO₂ of group V lungs (23°C) showed no significant decrease (105.2 ± 7.9 mm Hg at 10 minutes). Compared with group V, the group IV lungs (10°C) displayed a significant deterioration in PaO₂ (62.5 ± 11.7 mm Hg at 10 minutes; $p < 0.05$). Furthermore, whereas the PAP in group V was 12.7 ± 0.5 mm Hg at 10 minutes, the PAP in group IV was significantly increased to 19.0 ± 1.9 mm Hg at 10 minutes ($p < 0.05$). There was no difference in PaCO₂ and P_{aw} between groups IV and V.

Comment

Currently organ preservation is primarily based on reversible inhibition of the isolated organ's metabolism by

Fig 2. Arterial oxygen tension (PaO₂) of groups I through V at the end (at 10 minutes) of the reperfusion period.

Fig 3. Mean pulmonary arterial perfusion pressure (PAP) of groups I through V at the end (at 10 minutes) of reperfusion.

A

B

Fig 4. (A) Uniform and clean wash-out of the pulmonary vascular bed was easily obtained while the temperature of flushing solution was 23°C. (B) In contrast, it was quite difficult to establish uniform and clean wash-out of the pulmonary vascular bed if the temperature was 10°C.

hypothermia. There are two ways to achieve hypothermia: surface and flush cooling. Surface cooling is an inefficient method for reducing the core temperature of a large organ, especially for inflated lungs with the insulat-

ing effect of air. Inefficient cooling results in a longer period of warm ischemia. The detrimental effects of even a short period of normothermic ischemia on the lungs subsequently preserved by topical hypothermia are well recognized [3, 5, 6]. Moreover, when the blood supply to an organ is terminated, the following occur immediately: decrease in temperature, collapse of vascular system, and stasis of blood, particularly in the capillaries and venous system. Thus, the vasculature of an ischemic organ becomes progressively more difficult to perfuse as the duration of ischemia is prolonged. This is the so-called no-reflow phenomenon, and may be an important contributing factor to warm ischemic injury [7].

Flush preservation of the lungs may provide several advantages: (1) rapid cooling and shortening of the period of normothermic ischemia; (2) washout of pulmonary vascular blood, thus possibly preventing the no-reflow phenomenon and the production of toxic substances from the ischemic blood components; and (3) minimizing the adverse effects of cooling on cell physiology by the use of an appropriate flush solution. However, flushing with a crystalloid solution may, under some circumstances, be harmful if cellular or interstitial edema results.

It has been emphasized that of all the investigations pertinent to flush preservation of lung, none has given consistent and predictable results [2]. This lack of consistency raises the question that some factors, besides the composition of the flushing solution, may contribute to this inconsistency. The effects of temperature and volume of perfusate, flow and pressure during flushing, uniformity of flow distribution, and airway status during flushing have yet to be accurately defined.

Cooling can be immediately produced by a brief flush with a chilled electrolyte solution. However, an ill-understood phenomenon, "thermal shock," may occur whereby some cells are damaged by rapid cooling even without freezing. This phenomenon has long been known to occur in some microorganisms [8], spermatozoa [9], and modified erythrocytes [10]. In relation to organ preservation, Pegg and colleagues [3] have demonstrated a highly deleterious effect of rapid cooling (rate > 7.2 mL/min) in the rabbit kidney. Otto and co-workers [11] concluded that rapid cooling is an important pathophysiological mechanism in porcine liver preservation. Isselhard and his associates have studied skeletal muscle in rats and dogs and found that cooling to 0° to 2°C in 4 minutes impaired both metabolism and survival rate, whereas cooling to the same temperature in 90 minutes had an excellent preservation effect (unpublished results). Moreover, it has also been suggested that a rapid cooling rate might damage rat hearts [12].

From our previous studies [5], we found that the optimal temperature for lung preservation appears to be in the vicinity of 10°C. However, the optimal storage temperature may not necessarily be the optimal flushing temperature. Our results demonstrated that, functionally, the lungs flushed with LPD solution at 23°C were superior to those flushed at 10°C. Flushing of the lungs at low temperatures may cause vasoconstriction with high vascular resistance, thus disturbing the uniformity and com-

pleteness of the blood washout (Fig 4), even after premedication with prostaglandin E_1 . Furthermore, rapid cooling might impair the endothelial function and induce interstitial or cellular edema due to vascular spasm, or other undetermined mechanisms, but dilatation of the smooth muscle bed could occur with prostaglandin E_1 . However, it is difficult to determine whether this is due to a direct temperature effect on lung parenchyma or a vascular effect with a relatively poor quality of flushing.

The rabbit lung is so small that it is rather easy to cool down by immersion in cool solution. By placing a small probe thermometer into the right lung to continuously measure lung temperature, we found that it generally only took 2 to 3 minutes to cool down the rabbit lung from room temperature (23°C) to 10°C. However, for a large animal lung, this temperature change seems to have a different situation. It should take a longer time to cool the lung by simple immersion. Thus, theoretically, it may be advisable to sequentially change the temperature of flushing solution from room temperature (23°C) to the optimal lower temperature. In this way a uniform flushing and a shorter warm ischemic time of the preserved lung may be more easily achieved. However, further studies relative to the amount and compositions of flushing solution and the flow rate and pressure during flushing are also needed.

From this study, we conclude that in lung preservation, uniform flushing with LPD solution improved ischemic tolerance, as compared with simple topical hypothermia, and that flushing of lungs with low-temperature solution is likely to produce rapid cooling and a higher vascular resistance with incomplete blood removal from the ischemic lungs; each of these effects may adversely affect lung preservation.

Supported by MRC grant MA 6909.

We wish to express our appreciation for the expert technical assistance provided by John Mates and Elaine Murphy.

Male Donor Into Female Recipient Increases the Risk of Pediatric Heart Allograft Rejection

Motohiro Kawauchi, MD, Steven R. Gundry, MD, Javier Alonso de Begona, MD, David A. Fullerton, MD, Anees J. Razzouk, MD, Mark M. Boucek, MD, Sandra Nehlsen-Cannarella, PhD, and Leonard L. Bailey, MD

Loma Linda University Medical Center, Loma Linda, California

Sixty-one infants and children, 12 years old or younger, who received an orthotopic cardiac allograft between November 1985 and December 1989 were analyzed for the incidence of rejection. Rejection was diagnosed non-invasively within the first 3 months and during the first year. Rejection episodes were diagnosed by signs and symptoms according to previously reported criteria. Multiple regression analysis with recipient age, donor age, donor-recipient weight ratio, number of HLA mismatches, sex of the recipient, sex-encoded minor tissue antigen incompatibility (H-Y: female recipients receiving male donor organ), graft ischemic time, lowest cyclosporine level during the first 2 postoperative weeks, and prophylactic use of OKT3 showed that H-Y was the only significant contributing factor for rejection at 3 months and 1 year ($r = 0.308$, $p < 0.02$; $r = 0.308$, $p < 0.02$;

respectively). Patients were divided into two groups: group 1, 45 patients who were H-Y compatible (male and female recipients receiving female donor hearts); and group 2, 16 patients who were H-Y incompatible (female recipients with male hearts). Patients in group 2 had significantly more episodes of graft rejection than did patients in group 1 by 3 months and by 12 months after heart transplantation (3 months: 2.75 ± 1.48 versus 1.67 ± 1.41 , $p < 0.05$; 1 year: 4.80 ± 1.87 versus 2.59 ± 1.93 , $p < 0.01$; respectively). There were six grafts lost due to rejection in group 2 (6/15, 37.5%) and 7 grafts lost (7/45, 15.5%) in Group 1 (not significant). Heart transplantation with H-Y incompatibility resulted in a significantly greater incidence of rejection episodes.

(*Ann Thorac Surg* 1993;55:716-8)

It is recognized that antigenic differences at the major histocompatibility (MHC) complex play a significant role in clinical and experimental allograft rejection. However, grafts expressing minor non-MHC transplantation antigens may also be at risk for accelerated rejection. Such may be the case with the sex-specific transplantation antigen H-Y, a minor tissue antigen. For example, female mice of some strains reject skin grafts from male donors of the same strain [1-5]. Goulmeyer and co-workers [6, 7] reported the importance of H-Y (sex antigen) incompatibility in human bone marrow transplantation. Crandall and associates [8] reported increased cardiac allograft rejection in female heart transplant recipients, but did not evaluate specific H-Y incompatibility. The effect of recipient sex in clinical kidney transplantation is not clear [9-13]. In this report, we assess the importance of H-Y incompatibility between donor and recipient in pediatric cardiac transplantation.

Material and Methods

Patients

Pediatric patients up to 12 years old who received cardiac allografts between November 1985 and December 1989 at

Loma Linda University Medical Center were retrospectively reviewed. Of 71 patients who received 73 allografts in this period, 10 recipients (11 allografts) who died perioperatively for reasons other than rejection and one retransplantation are not included in this study. This study covers the 61 remaining patients.

The age of the recipients in this study was from 3 hours to 12 years (mean, 13.4 months). The indications for transplantation were hypoplastic left heart syndrome, 37; cardiomyopathy, 11; and other congenital cardiac anomalies, 13.

The surgical procedure, management, and postoperative immunosuppressive therapy are the same as previously reported [14-16]. Briefly, intravenous cyclosporine administration was started 6 hours preoperatively and maintained postoperatively at 0.1 mg/kg per hour. When oral feedings were well tolerated, intravenous administration of cyclosporine was discontinued and oral administration (4 to $15 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ in divided doses every 8 to 12 hours) was started. Azathioprine at $3 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ was also administered intravenously or orally. Corticosteroids were prescribed for 2 days perioperatively and for treatment of acute rejection episodes, which were diagnosed according to previously reported criteria using echocardiography, chest roentgenography, and clinical examination or suspicion [17]. Endomyocardial biopsies were used selectively in older children. Rejection episodes were initially treated with oral or intravenous administra-

tion of steroids. Antithymocyte globulin or OKT3 was administered for recurrent or for moderate to severe episodes. One young infant underwent successful retransplantation after rejection-induced acute failure of his primary graft.

Twelve patients died 4 months to 3 years after transplantation due to acute or chronic rejection.

Study Methods

Recipient age, donor age, donor/recipient weight ratio, number of HLA antigen mismatches, sex of the recipient, Y-chromosome incompatibility (H-Y), graft ischemic time, lowest cyclosporine level (postoperative day 0 to 14), and prophylactic use of OKT3 were retrospectively reviewed. The analysis attempted to detect correlation of any of the above parameters with the number of treated rejection episodes within the first 3 months and within the first year. Rejection episodes were defined as occurring whenever echocardiographic, clinical, or biopsy signs of rejection were actively treated or were found at autopsy. Multivariate regression analysis was employed for statistical assessment. No organs were transplanted across ABO blood group barriers, and no patient was presensitized to the specific donor. The 61 patients were divided into two groups: group 1, 45 patients without H-Y incompatibility (all male recipients and female recipients with female donor hearts); and group 2, 16 patients with H-Y incompatibility, ie, female recipients with male hearts. Rejection episodes at 3 months and 1 year and number of graft losses from rejection were compared between the groups. Additional statistical analysis included Student's *t* test and the χ^2 test. A *p* value less than 0.05 was considered to be significant.*

Results

Multiple regression analysis using the independent variables described in the previous section indicated that H-Y incompatibility was the only significant contributing factor to rejection at 3 months or 1 year ($r = 0.308$, $p < 0.02$; $r = 0.308$, $p < 0.02$; respectively). Equally important, we found no correlation between recipient age, donor age, donor/recipient weight ratio, number of HLA mismatches, sex of the recipient, graft ischemic time, low cyclosporine level, and prophylactic use of OKT3.

Patients with H-Y incompatibility (male donors into female recipients; group 2) showed significantly greater numbers of rejection episodes than those with H-Y compatibility (group 1). This was not only true during the first 3 months (episodes of rejection: 2.75 ± 1.48 versus 1.67 ± 1.41 , respectively; $t = 2.59$, $p < 0.05$) but also during the first year (4.80 ± 1.87 versus 2.59 ± 1.93 ; $t = 3.00$, $p < 0.01$). There were 6 graft losses from rejection in group 2 (6/16, 37.5%) and 7 graft losses (7/45, 15.5%) in group 1. This difference did not reach statistical significance ($\chi^2 = 3.39$).

Comment

It is widely accepted that female sex is a risk factor in several autoimmune diseases including systemic lupus erythematosus and thyroiditis. Before this study, we had anecdotally suspected that female sex was a risk factor for increased frequency of rejection in our pediatric heart transplant population. Indeed, it appears as though our impressions were correct, as female pediatric recipients of hearts do have more rejection episodes than other recipients. However, our study suggests that this conclusion is too simplistic, and this retrospective study illustrates that, in the pediatric population, H-Y incompatibility (male hearts into female recipients) accounts for this phenomenon. Recipient sex, per se, was not an independent variable favoring increased rejection, but the large number of female recipients of male donor hearts tipped the overall balance so that it appeared that female sex was an independent risk factor in this very early age group. But, among only female recipients, those with male hearts had more rejection episodes than those with female hearts (2.75 ± 1.48 versus 2.0 ± 2.0 within 3 months; 4.80 ± 1.87 versus 2.25 ± 3.20 within 1 year). This did not reach statistical significance because the number of female recipients with female donor hearts was small ($n = 5$).

Female sex as an independent variable did not reach statistical significance in the present study. Early age at the time of transplantation, with its implied lack of immunologic experience, may account for this finding. Older female patients with mature immunological response appear, in fact, to more aggressively reject their transplanted organ. In bone marrow transplantation, Goulmy and associates [7] reported that peripheral blood lymphocytes of an aplastic anemia patient with an H-Y incompatible donor bone marrow transplant were able to show HLA-restricted H-Y killing in a cell-mediated lymphocyte assay. A high incidence of female donor cell reactions to recipient H-Y antigen in HLA-matched bone marrow transplantation was also observed in the early postoperative period [18]. Sex matching of the donor and recipient was also considered to have a significant bearing on the survival of patients with aplastic anemia who received marrow transplantation from HLA-identical siblings [19].

Male-specific antigen is also considered to be an important histocompatibility antigen in clinical kidney transplantation when donor and recipient are HLA identical, or both are HLA-A2 positive [7, 9]. Conversely, Opelz and Terasaki [13] could find no donor sex-related difference in survival of kidney grafts. Indeed, maternal recipients of kidney grafts from their children showed better results than paternal recipients, although this may be the result of immunological moderation from pregnancy.

The number of HLA mismatches clearly influences the results of transplantation among male kidney recipients, especially non-O blood type individuals. The influence of these factors is further altered by multiple transfusions [13]. Kidney grafts from male donors into multiparous female recipients survived longer, but male grafts into nulliparous females did not [11]. Similarly, pregnancy in

inbred mice is associated with long-term acceptance of H-Y incompatible skin grafts, even in some "rejecter" strain females [20]. Thus, the importance of the H-Y minor antigen mismatch in renal transplantation may be obscured by more powerful transplantation antigens.

Crandall and co-workers [8] reported increased cardiac allograft rejection in female patients in a series of 140 heart transplant recipients. No differences were observed in mortality, but rejection episodes in the first 4 months were significantly more frequent in female recipients. They attributed those observations to (1) the possibility that the female possesses an intrinsically more vigorous immune system and (2) the possibility that these findings may be specific for immunosuppressive protocols that eliminate maintenance corticosteroids. They suggested that sex-related difference became less apparent when all recipients received maintenance corticosteroid therapy. Moreover, in adults, especially in adult kidney transplant recipients as mentioned above, pregnancy and multiple transfusions may modify the outcome.

In our series of pediatric patients, steroids were administered immediately postoperatively and then only for rejection episodes. This lack of broad immunosuppression by steroids may have allowed expression of immune response to less important transplantation antigens, such as the Y antigen mismatch. The antibody titer for male-specific antigen decreases at about 1 year after transplantation [7]. Thus, H-Y incompatibility may only influence the occurrence of graft rejection in the early transplant period. Indeed, rejection episodes are extremely rare more than a year after transplantation in both male and female patients in our population. Importantly, weak transplantation antigens, such as male-specific antigen, do not usually result in differences in mortality. Although we observed a difference in mortality that might be attributed to sex disparity, this difference has yet to reach statistical significance. For this reason, we have not routinely strengthened the immunosuppressive regimen in female patients receiving male donor hearts. Although the addition of steroids may blunt much of their additional rejection risks, maintenance steroids carry such long-term morbidity in infants and children that we continue to avoid their use whenever possible.

Finally, a potential weakness of this study is the use of the treatment of a suspected rejection episode as an objective measure of rejection. Although seemingly less concrete than an endomyocardial biopsy, we have previously shown an extremely strong correlation of the clinical suspicion of rejection by echography and physical/laboratory examination to endomyocardial biopsy [16]. Particularly in this population, in which repeated venous access is limited, the thoroughness with which rejection is sought for clinically justifies this technique as a measurement of rejection episodes.

In conclusion, based on our study of 61 infant and pediatric heart transplant recipients, we have found that a mismatch of the Y antigen (H-Y incompatibility) that occurs when a male donor heart is transplanted into a

female recipient significantly increases the number of rejection episodes during the first 3 months and 1 year after transplantation. Although there is a suggestion that late mortality is also increased in patients with this mismatch, this conclusion must await a larger patient volume and follow-up. Because of the very contracted donor pool, we continue to place male hearts into female recipients, but these children are monitored closely and treated aggressively for rejection.

Severe Ischemic Left Ventricular Failure: Coronary Operation or Heart Transplantation?

Giovanni B. Luciani, MD, Giuseppe Faggian, MD, Renato Razzolini, MD, Ugolino Livi, MD, Uberto Bortolotti, MD, and Alessandro Mazzucco, MD

Department of Cardiovascular Surgery and Cardiology, University of Padova, Padova, Italy

Severe left ventricular failure in ischemic heart disease may contraindicate conservative surgical procedures. To redefine therapeutic indications, the clinical and angiographic data of 143 patients (137 men and 6 women) with ischemic heart disease and a left ventricular ejection fraction less than 0.30 who were seen by us between June 1985 and December 1990 were retrospectively analyzed. Patients were divided into three groups according to therapy: medical only, 72 (group 1); myocardial revascularization, 20 (group 2); and heart transplantation, 51 (group 3). Clinical status was poorer in group 3, with congestive heart failure as predominant symptom; angina was more frequent in group 2. No difference was noted in hemodynamic variables. Four early deaths

(20.0%) occurred in group 2 and 7 (13.7%) in group 3. Follow-up ranged from 1 to 64 months (mean, 22 ± 19 months), with an actuarial survival of $28\% \pm 9\%$, $80\% \pm 8\%$ and $82\% \pm 5\%$ at 5 years in groups 1, 2, and 3, respectively. Even though postoperative New York Heart Association class was better in group 3 (1.0 versus 2.3 in group 2; $p < 0.01$), the difference in survival was not significant. Although in patients with ischemic heart disease and low left ventricular ejection fraction heart transplantation offers the best clinical results, considering the donor shortage, we conclude that myocardial revascularization may still be performed with good mid-term results.

(*Ann Thorac Surg* 1993;55:719-23)

Heart transplantation (HTx) has gained widespread acceptance as a valid therapeutic alternative for patients with end-stage ischemic heart disease [1]. The improvement in survival and quality of life after heart transplantation, mainly due to safer immunosuppression and better patient management, has led to a steady growth of the recipient pool [1]. Unfortunately, the number of available donors has remained chronically insufficient [2] and, currently, more than 35% of the heart transplant candidates die while on the waiting list [3].

Myocardial revascularization has also benefited from improved technological advances and patient management, likewise resulting in improved survival [4]. Thus, patients previously considered at prohibitive risk for

clinical and angiographic variables, we attempt to identify criteria that might be useful in selecting patients either for conservative operation or for HTx.

Material and Methods

From June 1985 to December 1990, 143 patients with ischemic cardiomyopathy were referred to our institution. All had angiographic evidence of multiple critical coronary lesions and a left ventricular ejection fraction (LVEF) less than 0.30; patients with left ventricular aneurysm were excluded from this study. The 137 men and 6 women were divided into three groups according to the type of therapy: 72 patients received medical therapy only (group 1), 20 underwent myocardial revascularization (group 2), and 51 had HTx (group 3). The patients in group 1 included 45 patients referred for HTx and 27 patients belonging to a cardiological series, for whom only medical treatment was initially advised; 20 of these patients were subsequently offered CABG but refused this option. The remaining patients were nonrandomly distributed between groups 2 and 3.

The clinical profile of patients is illustrated in Table 1. Although age and sex of the patients in the three groups were comparable, group 3 patients were in significantly poorer clinical condition compared with patients in the other groups. The predominant symptom was also different among patients: severe angina refractory to medication was significantly more frequent in group 2 ($p < 0.01$), whereas congestive heart failure was more common in group 3 ($p < 0.01$). Ventricular arrhythmias (including multiple premature complexes, tachycardia, and ventric-

For editorial comment, see page 581.

surgical revascularization may undergo coronary artery bypass grafting (CABG) with low operative mortality and a successful long-term outcome [4, 5]. Therefore, a definition of the selection criteria of patients with end-stage ischemic heart disease for either myocardial revascularization or HTx has become increasingly important. In this article, we present the midterm clinical results obtained in three groups of patients with ischemic heart disease and severe left ventricular failure (ejection fraction < 0.30) who were treated with medical therapy only, revascularization, or HTx. Moreover, by retrospective analysis of

CHF = congestive heart failure; NS = not significant; NYHA = New York Heart Association.

ular fibrillation) were documented by electrocardiography in about half of the patients in groups 1 and 3, being less frequent in group 2 ($p < 0.01$).

Angiographic data at admission are summarized in Table 2. The extent of left ventricular failure is evidenced by the low LVEF, the large left ventricular end-diastolic volume, and the high mean pulmonary artery pressure in all groups. None of the variables analyzed was significantly different between groups.

The majority of group 1 patients were receiving digitalis in association with either diuretics (55%) or vasodilators, including nitrates (35%); few patients (<10%) were receiving vasodilators only.

Five patients (25%) in group 2 were on intravenous inotropic support or an intraaortic balloon pump preoperatively. All patients in group 2 underwent CABG, with a mean number of 2.2 grafts per patient. In 30% of patients CABG was associated with other surgical procedures: postinfarction ventricular septal defect repair in 3 patients (15%), mitral valve annuloplasty in 2 (10%), and mitral valve replacement in 1 (5%).

Surgical therapy in group 3 included orthotopic HTx in 44 patients and heterotopic HTx in 7. Twelve of these

patients (24%) had previous operations: CABG (10 patients) and CABG associated with mitral valve annuloplasty (2 patients). Only 3 patients (6%) required intravenous inotropic support or mechanical assist before transplantation.

Midterm cardiac function was assessed by means of clinical examination (New York Heart Association [NYHA] functional class at follow-up) and mean LVEF at last follow-up echocardiography in all patients. Because all patients undergo angiography on a yearly basis after HTx, angiographic data were also available in group 3.

Standard statistical methods used included Student's *t* test for paired and nonpaired data for comparison of continuous variables, Pearson's χ^2 for discrete variables, and the Wilcoxon rank-sum test for follow-up periods. The Kaplan-Meier method and the corresponding log-rank test were used for survival, whereas univariate (χ^2 and Wilcoxon rank-sum) analysis was used to identify variables predictive of mortality. The variables tested included age, sex, NYHA class, angina, congestive heart failure, LVEF, left ventricular end-diastolic volume, cardiac index, pulmonary artery pressure, and therapy. A value of *p* less than 0.05 was considered significant.

Table 2. Angiographic Data at Admission^a

Variable	Group 1 (n = 72)	p Value (1 vs 2)	Group 2 (n = 20)	p Value (2 vs 3)	Group 3 (n = 51)	p Value (3 vs 1)

^a All values are shown as mean ± standard deviation. ^b Student's *t* test. ^c Pearson's χ^2 .

CI = cardiac index; LVEDV = left ventricular end-diastolic volume; LVEF = left ventricular ejection fraction; mitral regurgitation = mild to moderate insufficiency; NS = not significant; PAP = mean pulmonary artery pressure.

Fig 1. Actuarial survival of patients with severe ischemic left ventricular failure according to type of treatment. The dotted line depicts survival of patients undergoing heart transplantation (51); the solid line, survival of patients undergoing myocardial revascularization (20); and the broken line, survival of patients receiving medical therapy only (72). The percentage numbers at the end of each line represent actuarial survival for each group of patients at follow-up (64 months).

Results

Survival

There were 38 deaths in group 1 throughout follow-up; 19 (50%) were in patients referred for HTx who died on the waiting list. All deaths were of cardiac origin. Although 14 deaths were sudden, likely due to malignant ventricular arrhythmias, 20 were the result of either congestive heart failure or infarction; in 4 patients the cause of death was unknown.

There were four (20.0%) (70% confidence interval, 10% to 33%) early deaths (within 30 days of operation) in patients undergoing myocardial revascularization. All deaths occurred perioperatively, due to low output syndrome in critical patients on inotropic or intraaortic balloon pump support preoperatively. In 2 of these patients CABG was associated with repair of a large postinfarction ventricular septal defect. There were no deaths among the 3 patients undergoing CABG and mitral valve operation. Thus, the overall mortality of patients undergoing CABG without associated procedures was 14.3%, whereas the mortality in the group of patients having CABG and ancillary procedures reached 33.3%. Four additional patients required an intraaortic balloon pump postoperatively and were successfully weaned from it. No late deaths occurred in group 2 during follow-up. There were seven (13.7%) (70% confidence interval, 9% to 20%; group 2 versus group 3, $p =$ not significant) early deaths among the transplant recipients; six deaths (11.6%) (70% confidence interval, 7 to 18) occurred perioperatively. The cause of death was acute graft failure in 3 patients, right ventricular failure in the presence of high pulmonary vascular resistance in 2, and acute rejection in 1. One patient died at home suddenly 2 weeks after successful HTx. There was only one late death in group 3; it was caused by chronic rejection 15 months after HTx. No difference was noted between mortality after orthotopic HTx (13.6%; 6/44) and mortality after heterotopic HTx (14.3%; 1/7; $p =$ not significant).

Group 1 patients had a mean follow-up of 20 ± 17 months (range, 1 to 64 months) with an actuarial survival of $28\% \pm 9\%$ at 5 years. Group 2 patients had a mean follow-up of 34 ± 24 months (range, 1 to 64 months) with an actuarial survival of $80\% \pm 8\%$ at 5 years. Group 3 patients had a mean follow-up of 21 ± 16 months (range, 1 to 64 months) with an actuarial survival of $82\% \pm 5\%$ at 5 years. Although the difference in survival between patients receiving medical therapy and patients undergoing cardiac operation was highly significant ($p < 0.001$), no difference was found between conservative operation and heart transplantation (Fig 1).

Retrospective analysis of clinical and angiographic variables demonstrated that the type of treatment was the only variable that was predictive of mortality when the three groups were compared.

Midterm Cardiac Function

Current clinical status was assessed in all groups. Cardiac function of survivors in the medical group had deteriorated at follow-up: whereas 17% of patients were in NYHA class IV and 70% in class III at admission, 90% of them were in class IV and only 10% in class III at follow-up. The mean NYHA functional class was significantly higher when compared with the value at the beginning of the study and with the values in the other groups (Table 3). Progression of the disease was also documented by the decrease in mean LVEF at last echocardiography (Table 4).

The clinical condition significantly improved after myocardial revascularization; only 33% of patients were in NYHA class III and 67% in class II postoperatively, as opposed to 10% in class IV and 85% in class III at admission. Although most patients remained mildly symptomatic and their cardiac function was mildly depressed, the mean postoperative NYHA class and the mean LVEF evidenced a significant improvement from preoperative condition (see Tables 3, 4).

Table 3. NYHA Functional Class at Follow-up^a

Variable	Group 1 (n = 72)	p Value (1 vs 2)	Group 2 (n = 20)	p Value (2 vs 3)	Group 3 (n = 51)	p Value (3 vs 1)
NYHA class begin FU	3.1 ± 0.6	NS	3.2 ± 0.4	<0.01	3.8 ± 0.4	<0.01
p Value (begin vs end FU)	<0.01		<0.01		<0.01	
NYHA class end FU	3.9 ± 0.5	<0.01	2.3 ± 0.6	<0.01	1.0 ± 0.1	<0.01

^a All values are shown as mean ± standard deviation; p values were determined by Student's *t* test.

FU = follow-up; NS = not significant; NYHA = New York Heart Association.

The best functional results were obtained with HTx: 77% of patients were in NYHA class IV and 33% in class III before HTx and all of them shifted to class I postoperatively. Mean post-HTx NYHA class favorably compared with the pretransplantation value and with the postoperative class after CABG (see Table 3). Angiography was performed in 39, 28, 19, and 9 patients at 1, 2, 3, and 4 years after HTx, respectively. All patients but 1 were free of chronic rejection at follow-up, with a mean LVEF of 0.64 ± 0.05 , 0.62 ± 0.04 , 0.63 ± 0.06 , and 0.62 ± 0.07 at 1, 2, 3, and 4 years, respectively. The last echocardiographic examination in all patients showed a normal mean LVEF, significantly improved from the pretransplantation value (see Table 4).

Comment

The validity of HTx as therapeutic alternative for patients with end-stage ischemic heart disease is well established [1]. The success of transplantation occurred as a result of the introduction of cyclosporine in clinical practice, improvements in the selection of recipients and donors, and better management of the complications of immunosuppression [1, 6]. The excellent clinical results of this procedure favored a substantial expansion of the selection criteria for recipients [1]. Thus, in spite of the limited availability of donors, a great increase in the number of transplant candidates ensued [3]. Currently, more than 35% of patients die while waiting for a suitable donor [3]. Along with transplantation, the results of myocardial revascularization have also benefited from improved patient management and surgical techniques [4]. Myocardial revascularization has been shown to dramatically improve early and late survival in patients with severe left ventricular dysfunction [5, 7-10]. Regional ventricular function has also been found to improve after revascularization [11]. To optimize the donor pool and to give patients with nonischemic end-stage cardiac disease a better chance for

transplantation, the therapeutic indications for patients with severe ischemic ventricular dysfunction need to be defined.

Our experience shows that in patients with ischemic heart disease and depressed LVEF medical therapy only offers very poor results. The results presented here demonstrate higher survival when compared with the data published by Franciosa and associates [12] and by Wilson and colleagues [13] on prognosis of patients with end-stage heart disease. Consequently, it might be argued that not all medically treated patients were potential candidates for transplantation at admission in the study. However, it has been shown that many patients with "insufficient" symptoms for HTx still have a very dim outlook: indeed, arrhythmias were found to be a poor prognostic sign in patients with cardiomyopathy [14, 15]. Accordingly, the midterm survival of our medical series substantially agrees with recent works by Harris and co-workers [17] and by Califf and associates [17] showing a 5-year survival rate of about 30% in patients with severe ischemic left ventricular failure assigned to medical therapy. Furthermore, the absence of a significant difference in quantitative angiographic data between groups indicates that the majority of group 1 and group 2 patients might have been candidates for cardiac transplantation. Besides therapy, no clinical or angiographic variable was found to correlate with higher mortality in the medically treated patients.

Myocardial revascularization in patients with severe left ventricular failure yielded good midterm survival and acceptable functional results. Operative mortality seemed higher in our series when compared with the large randomized studies on coronary artery operation [5, 9, 10]. However, none of these studies considered revascularization in patients with severe ventricular failure who also needed associated surgical procedures (mitral valve repair or replacement, repair of a ventricular septal defect). The need for associated cardiac procedures and the poor

Table 4. Cardiac Function at Follow-up^a

preoperative clinical conditions are recognized incremental risk factors for operative mortality [18]. Accordingly, half of our operative deaths occurred in patients undergoing CABG and repair of a ventricular septal defect; in addition, all patients who died early were on an intraaortic balloon pump preoperatively. In fact, our survival data favorably compare with the reported results of myocardial revascularization in high-risk patients awaiting HTx [18-21]. Functional outcome after CABG was acceptable in our series: even if clearly poorer than after transplantation, clinical condition significantly improved after revascularization. Analysis of preoperative variables showed that the predominant symptom in these two groups of patients differed: angina refractory to medical therapy was more common in group 2 and congestive heart failure in group 3. These findings support previous evidence showing that in patients with poor left ventricular function preoperative angina might predict a good result after CABG [8, 20, 22]. Further, considering that the presence of angina in patients with ischemic cardiomyopathy suggests the existence of viable myocardium [22], these results also agree with those by Louie and co-workers [21], who showed that reversible myocardial ischemia at positron emission tomography predicts successful revascularization. Indeed, our limited series indicates that in the presence of bypassable vessels, angina may be the single most reliable criterion to assign patients with ischemic end-stage heart failure to revascularization rather than HTx.

Even though HTx yielded the best survival and functional results, it must be emphasized that as many as 19 patients with severe ischemic left ventricular failure who were initially referred for HTx (10% of all patients enlisted for HTx) died while on the waiting list during the study. Thus, the good midterm outlook after HTx should always be weighed against the limited donor availability [3]. In conclusion, although medical treatment alone bears high mortality in patients with ischemic left ventricular failure and should be reserved only for patients with absolute contraindications to CABG or HTx, revascularization and transplantation offer good and comparable midterm survival. Although operative mortality of conservative cardiac operation is higher and functional results are poorer when compared with HTx, particularly considering the current shortage of donors, all patients with ischemic heart disease and severe left ventricular failure with angina as a leading symptom should be evaluated for myocardial revascularization as an initial procedure.

Cardiopulmonary Bypass and Pulmonary Thromboxane Generation

Tajammul Shafique, MD, Frank W. Sellke, MD, Robert L. Thurer, MD, Ronald M. Weintraub, MD, and Robert G. Johnson, MD

Division of Cardiothoracic Surgery, Beth Israel Hospital, Harvard Medical School, and Charles W. Dana Research Center, Boston, Massachusetts

Sporadic cases of inexplicable noncardiogenic pulmonary edema occur after operations requiring total cardiopulmonary bypass (CPB). Prostaglandins, such as thromboxane (Tx) A_2 , have been implicated in this form of pulmonary pathology in many clinical and experimental settings. Because Tx generation has been demonstrated in association with ischemia of solid organs, we postulated that total CPB, which decreases pulmonary tissue perfusion and oxygenation, would stimulate local Tx synthesis. Total CPB was examined in 7 sheep. The level of TxB_2 (a stable metabolite of the active, unstable A_2) was measured in the left and right atria before, during, and after 105 minutes of total CPB. Significant increases in TxB_2 concentrations occurred in the left atrium compared with the right ($p < 0.05$) during CPB. Immediately after reperfusion, both the left atrial and right atrial TxB_2 concentrations increased significantly over the baseline values ($p < 0.05$), but this increase and the atrial gradient

were rapidly abolished with continued pulmonary perfusion. To determine the effect of extracorporeal circulation without significant ($<30\%$) alteration in pulmonary perfusion, we evaluated the effect of partial CPB in 5 sheep. Increased TxB_2 concentrations were noted at 15 and 30 minutes after the onset of partial CPB (left atrium increased significantly over baseline; $p < 0.05$), but this elevation spontaneously diminished to insignificance after 15 and 30 additional minutes of extracorporeal circulation. These data establish that total CPB stimulates Tx generation in the lung, and although the effect of partial CPB is transient, that of total CPB is progressive and abolished by reperfusion. Although the local pathophysiological effects of pulmonary Tx generation after CPB remain to be determined, this study may provide insight into a mechanism for sporadic, noncardiogenic pulmonary edema after CPB.

(*Ann Thorac Surg* 1993;55:724-8)

Arachidonic acid derivatives, including thromboxane (Tx), are being implicated increasingly as important mediators and modulators of pathophysiological processes in the lungs [1]. Cardiopulmonary bypass (CPB) is associated with an increase in systemic Tx levels [2], but the site and cause of its synthesis in this situation are speculative and have not been rigorously investigated.

Total CPB, as used clinically, results in nearly complete diversion of pulmonary blood flow and the cessation of ventilation. The absence of these two sources of oxygen makes the lung tissue dependent on the variable supply from the bronchial arteries during CPB. Although the oxygen requirement of lung tissue is not great during this time, the lack of pulmonary blood flow might have significant pathophysiological effects. Ischemia is known to stimulate Tx production from other tissues [3, 4], and lungs are a known rich source of this substance [5, 6]. We hypothesized that during total CPB Tx is generated by the lungs rendered ischemic because of their circulatory exclusion and nonventilation.

Material and Methods

Anesthesia and Operation

Dorset-Rambouillet cross-breed female sheep ($n = 12$) weighing 27 to 37 kg (mean weight, 31.5 kg) were premedicated with atropine and anesthetized with intravenous α -chloralose, 80 mg/kg, and urethane, 500 mg/kg. Animals were intubated and mechanically ventilated (Harvard apparatus, Millis, MA). Arterial blood gas and pH were measured during the procedure (pH Blood gas analyzer 1306; Instrument Lab, Lexington, MA) and maintained within physiological limits (pH, 7.35 to 7.42; 100 mm Hg $<$ oxygen tension $<$ 300 mm Hg; 35 mm Hg $<$ carbon dioxide tension $<$ 45 mm Hg). Systemic arterial and central venous pressures were monitored by percutaneous cannulation of the femoral artery and internal jugular vein. In one group of animals ($n = 7$) a left thoracotomy was performed and the main bronchoesophageal artery was identified [7, 8] and isolated. A sternotomy was then performed, and after systemic heparinization (400 IU/kg), cannulas were placed in the right atrium and aorta in preparation for cardiopulmonary bypass. Large-bore catheters were introduced into the left and right atria so that paired, serial samples could be drawn for determination of TxB_2 (a stable, inactive metabolite of the physiologically active but unstable TxA_2) concentration. The extracorporeal circuit consisted of a roller pump

(Cardiovascular Instrument Corp, Wakefield, MA), and bubble oxygenator (Bentley Bio-2; Baxter Health Care Corp, Irvine, CA). The circuit was primed with Ringer's lactate solution (25 mL/kg).

Animals were cared for in accordance with the guidelines established by the Beth Israel Hospital's Committee on Animal Research and those prepared by the Committee on the Care and Use of Laboratory Animals of the Institute of Animal Resources, National Research Council (DHHS publication No. 85-23, revised 1985). The Beth Israel Hospital animal research facility is fully accredited by the AAALAC.

Experimental Groups

The study consisted of two experimental groups. In the first group (total CPB group), the effect of CPB-induced ischemia of the lungs on TxB_2 profile across the pulmonary circuit was examined. Subsequently, in a second group of animals (partial bypass group), the change in TxB_2 levels was examined during an identical period of extracorporeal circulation, with a minimal degree of pulmonary ischemia (maintenance of >70% pulmonary arterial flow).

TOTAL CARDIOPULMONARY BYPASS GROUP ($n = 7$). In this group, animals were placed on total CPB and, after initial stabilization, the pulmonary artery was clamped and ventilation was halted. Arterial flow was maintained at 80 to 100 $\text{mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and regular blood gas analysis was performed to assess the adequacy of perfusion and gas exchange. Paired serial samples were taken from the left atrium and the right atrium for Tx assay 15, 30, 45, and 60 minutes after commencement of CPB. For the purpose of comparison, simultaneous samples were also obtained from the aortic cannula at different intervals during this period. Thereafter, the bronchial artery was clamped. No sampling was done during this time as left atrial blood return decreased to a minimal level. After 45 minutes of bronchial artery occlusion, CPB was terminated, pulmonary and bronchial artery clamps were removed, and ventilation was resumed. Serial paired samples were taken from the left and right atria immediately and at 10, 25, and 50 minutes after pulmonary reperfusion.

During total CPB and before bronchial artery occlusion, the volume of blood returning to the left heart was measured by placing a wide-bore catheter in the left ventricular cavity. This gave an estimate of bronchial flow in each animal.

PARTIAL CARDIOPULMONARY BYPASS GROUP ($n = 5$). In this group, animals were placed on CPB as above, but less than a third (25 mL/kg) of estimated cardiac output was allowed to flow through the extracorporeal circuit. Partial bypass was achieved by setting a previously calibrated roller pump to the desired output (25 mL/kg). Gravity-assisted venous return was controlled by adjusting the height of draining reservoir (bubble oxygenator) to equal the pump output. Because most of the venous return was allowed to flow through the pulmonary artery and the lungs were ventilated normally, there was no significant

pulmonary ischemia. Paired serial samples were collected from the right and left atria 15, 30, 45, 60, and 90 minutes after the onset of extracorporeal circulation. Cardiopulmonary bypass was then terminated and paired samples were again taken from the right and left atria immediately and at 10, 25, and 50 minutes after termination of bypass.

Sample Collection and Thromboxane Assay

Samples were collected by gentle aspiration from large-bore catheters placed in both atria; the initial 5 mL was discarded to account for dead space. Two-milliliter samples were placed in ice-cooled siliconized tubes containing 100 μL of 0.1 mol/L EDTA and 0.05% (wt/vol) aspirin in a ratio of 2:1. The hematocrit was measured in each sample to permit correction for hemodilution. Samples were immediately centrifuged at 4°C for 20 minutes at 2,000 g. Plasma was separated and stored in polypropylene test tubes at -25°C till assayed. All TxB_2 assays were performed within 2 weeks of experiment. Prior viability studies had shown no significant change in Tx levels for up to 8 weeks with this method of storage.

Thromboxane B_2 is a stable, inactive metabolite of the physiologically active but unstable TxA_2 , the half-life of which is 30 seconds at 37°C in aqueous solution [9]. We measured TxB_2 levels using a competitive binding radioimmunoassay. Anti-thromboxin B_2 antibody (rabbit), iodine 125-labeled TxB_2 tracer, TxB_2 standard, bovine serum albumin phosphate buffer, and magnetic goat anti-rabbit immunoglobulin G antibody were obtained from Advanced Magnetix Inc, Cambridge, MA. Assays were carried out according to the manufacturer's instructions. All results were expressed as picograms per milliliter.

We did not perform prostaglandin extraction from our samples, as falsely high levels have been reported after this procedure [10]. Cross-reactivity of anti- TxB_2 antibody with other prostaglandins is less than 1%. Thromboxane levels vary between individuals, as has been reported by other investigators [11, 12]. We used an external standard of plasma with known TxB_2 level for quality control.

Statistical Analysis

Values are expressed as mean $\pm$ standard error of the mean. In each group as a whole, differences in left atrial TxB_2 concentration compared with right atrial TxB_2 concentration were evaluated by two-way analysis of variance. Scheffé's multiple comparison test was applied to locate main sites of left atrial versus right atrial difference during CPB and reperfusion stages in both groups. Newman-Keul's multiple-sample comparison test was used to evaluate differences in TxB_2 levels compared with baseline in both the right atrium and the left atrium. Significance was determined at p less than 0.05.

Results

Total Cardiopulmonary Bypass Experiments

Figure 1 summarizes the results of the total bypass group. After introduction of cannulas in the right atrium and aorta, there was minimal change in left atrial and right atrial TxB_2 levels compared with baseline. With the onset

Fig 1. (A) Thromboxane B₂ (TxB₂) concentration in paired samples simultaneously drawn from the right atrium (RA) and left atrium (LA) before instrumentation (baseline [B LINE]), after cannulation of right atrium and aorta (postcannulation [PC]), and 15, 30, 45, and 60 minutes after the onset of total cardiopulmonary bypass (CPB) ($n = 7$). (B) Thromboxane B₂ concentration in paired samples simultaneously drawn from the right and left atria, before instrumentation, after cannulation of right atrium and aorta, and at intervals after reperfusion (R) of the pulmonary artery (at reperfusion = 0 minutes, then at 10, 25, and 50 minutes after termination of CPB). Time on total CPB = 105 minutes ($n = 7$).

of total CPB, there was a progressive increase (see Fig 1A) in TxB₂ levels in samples obtained from the left atrium (representing bronchial flow). There was also a slight, though not statistically significant, increase in right atrial TxB₂ levels, which was not sustained beyond the initial 15 minutes of CPB. Thus, an increasing gradient of TxB₂ levels between the left and right atria was documented during 60 minutes of CPB. Comparison between aortic cannula samples and those obtained simultaneously from the left and right atria at different intervals confirmed (Table 1) that TxB₂ levels at the aortic cannula site were similar to those in the right atrium (no increase across the bypass circuit) and significantly lower than left atrial levels ($p < 0.05$). The increase in left atrial TxB₂ concentration as compared with the right atrial concentration demonstrates an increase in TxB₂ level across the pulmo-

Table 1. Simultaneous Thromboxane Concentrations^a

Sample site	Thromboxane B ₂ (pg/mL)		
	Sample 1	Sample 2	Sample 3
Right atrium	287 ± 88	311 ± 89	243 ± 50
Aortic cannula	268 ± 68	260 ± 73	274 ± 76
Left atrium	537 ± 163	558 ± 178	570 ± 136

^a Thromboxane concentration in simultaneously drawn samples from the right atrium, aortic cannula, and left atrium at three predetermined intervals during cardiopulmonary bypass to establish whether a thromboxane concentration gradient might exist across the pump circuit (right atrium to aortic cannula) ($n = 7$). Values are shown as mean ± standard error of the mean.

nary circuit while only bronchial flow is present. During total bypass, before bronchoesophageal trunk occlusion, the mean left ventricular return was 1.08 ± 0.15 mL · min⁻¹ · kg body wt⁻¹, and for any given animal this flow remained constant during CPB. As some left ventricular thebesian return is included in this measurement, the actual bronchial flow would be slightly less than this mean value. Additionally, although more than 85% of the bronchial arterial supply in sheep is reportedly from the bronchoesophageal trunk, there is a right upper lobe bronchial artery that contributes the balance of bronchial flow [7]. In all of our animals there was a marked decrease in the left ventricular return after bronchoesophageal trunk occlusion.

At the onset of pulmonary reperfusion, after total CPB, significantly elevated levels of TxB₂ were immediately apparent in the left atrium and the right atrium compared with their respective control values. Subsequent samples taken 10, 25, and 50 minutes after reperfusion showed a rapid decrease in TxB₂ levels on both sides and abolition of the gradient between the atria (see Fig 1B).

Partial Cardiopulmonary Bypass Experiments

Figure 2 summarizes the results of the partial bypass group. The TxB₂ samples from this group were processed simultaneously in a batch subsequent to the samples from the total CPB group. The baseline values in this series of experiments were consistently higher than in the total CPB series, and comparisons are made only within the respective groups. With commencement of partial CPB there was an increase in TxB₂ level in both atria for the first 15 minutes, at which point right atrial TxB₂ values reached a plateau but the left atrial TxB₂ level continued to rise (see Fig 2A). After 45 minutes, however, there was a spontaneous decrease in TxB₂ levels. Only left atrial TxB₂ levels at 30 and 45 minutes showed a statistically significant increase compared with control, but there was no significant difference between left atrial and right atrial levels of TxB₂ at any time. Termination of partial CPB and complete reperfusion of lungs in this group did not significantly (see Fig 2B) affect TxB₂ levels on either side or the gradient between them.

Comment

Prostaglandins, including thromboxane, have a short half-life, and they are intercellular messengers [9]. These

Fig 2. (A) Thromboxane B₂ (TxB₂) concentration in paired samples simultaneously drawn from the right atrium and left atrium (LA) before instrumentation (baseline [B LINE]), after cannulation of right atrium and aorta (postcannulation [PC]), and 15, 30, 45, 60, and 90 minutes after the onset of partial cardiopulmonary bypass (CPB) (n = 5). (B) Thromboxane B₂ concentration in paired samples simultaneously drawn from the right and left atria before instrumentation, after cannulation of right atrium and aorta, and at intervals after cessation of partial CPB (immediately after = 0, then at 10, 25, and 50 minutes). The total period of partial CPB = 90 minutes (n = 5). (R = pulmonary reperfusion.)

important mediators and modulators of inflammation are therefore most effective near the site of their production. If thromboxane plays a role in pulmonary pathophysiology, we would presume that it is synthesized in the lung and that the production would be stimulated by events associated with that pathophysiology. There is abundant evidence that different cell types in lung tissue possess the enzyme system necessary to synthesize thromboxane *in vitro* [5, 6]. Similarly, *in vivo* thromboxane generation by lungs in response to diverse stimuli has been documented in many clinical and experimental studies [13-18].

We hypothesized that thromboxane is produced in the lungs in association with the pulmonary ischemia of total CPB. Our results show an increasing difference in TxB₂ concentration between the left atrium and the right atrium with increasing time on total CPB (see Fig 1A). Because

right atrial TxB₂ levels were the same as aortic cannula levels during total bypass (see Table 1), there is no evidence for TxB₂ generation in the pump itself, and the right atrial concentrations can be considered to represent the TxB₂ concentration in bronchial arterial blood, which is the source of pulmonary tissue perfusion during CPB. With the termination of CPB and reperfusion of the pulmonary artery, high TxB₂ concentrations were observed in left atrial samples, but these rapidly decreased toward baseline (see Fig 1B). Thus, there is clear evidence of TxB₂ synthesis in the lung during total CPB, which continues only briefly or is "washed out" in the first few minutes of reperfusion. Although this study demonstrates that Tx generation occurs *in* the lung during total CPB, we cannot conclude that it is produced by the lung tissue itself. The specific cellular source that is stimulated may include sequestered platelets, white cells, or pulmonary endothelial cells.

To observe the effect of a similar period of extracorporeal circulation on systemic TxB₂ levels without concurrent pulmonary artery flow deprivation, we repeated a similar protocol in animals on partial CPB. We found that Tx generation in response to extracorporeal circulation alone (partial CPB) is self-limited, lasting 30 to 45 minutes (see Fig 2A), and its cessation is unrelated to any reperfusion phenomenon. This pattern is similar to the one observed by Peterson and associates [16] and Townsend and colleagues [11] in a veno-venous bypass model. The underlying mechanism of Tx generation in this situation may be systemic effects of extracorporeal circulation, for example, platelet activation and sequestration [2, 19, 20] or complement activation and polymorphonuclear leukocyte interaction [21]. The transient TxB₂ concentration elevation, with no significant left atrial to right atrial gradient, that occurs with partial CPB cannot entirely explain the TxB₂ concentration changes seen in the animals with total CPB.

The increased TxB₂ production associated with total CPB (see Fig 1A) and abolished by pulmonary reperfusion (see Fig 1B) suggests that the mechanism of this generation is related to blood flow through the lungs. It has been observed that tissue ischemia is a stimulus to Tx generation [3, 4]. Kobinina and associates [22] showed a linear relationship between cardiac anaerobiosis and Tx generation in their cardioplegia experiments. The basic stimulus to TxB₂ synthesis during ischemia may be hypoxia of the lung, or it may be directly related to reduced tissue perfusion.

Oxygen requirements of the lung are small (2% to 5% of total oxygen consumption [23]) but essential for its metabolic integrity [24]. Diversion of pulmonary blood from unventilated lungs leaves bronchial flow as the sole source of oxygen to the lungs. As bronchial flow is known to be inconstant [25, 26], there is a distinct possibility of hypoxia in pulmonary tissue during total CPB, with consequent pulmonary injury.

Ratliff and associates [27] observed that after CPB, pulmonary injury was related to lung tissue polymorphonuclear leukocyte infiltration and the duration of bypass. Chenworth and colleagues [28] also concluded that transpulmonary leukosequestration after CPB was related to aortic

cross-clamping time. The relationship between the duration of CPB, pulmonary polymorphonuclear infiltration, and subsequent pulmonary injury may be explained on the basis of generation of humoral mediators of inflammation by the ischemic lungs. Thromboxane increases in vitro polymorphonuclear diapedesis and chemotaxis [29], mediates diapedesis after ischemia through regulation of polymorphonuclear cells [30], and also causes ischemia-induced neutrophil activation, manifested by H_2O_2 production [31]. Thus, Tx is capable of mediating inflammatory reaction in the lungs. It remains to be established whether the increased concentration of Tx seen in these experiments might be pathophysiologic. Certainly, sporadic and unexplained noncardiac pulmonary edema may occur after operative procedures requiring CPB. The unexpected occurrence of such injury in previously healthy lungs raises the question of pulmonary parenchymal injury associated with CPB. The demonstration of Tx generation by the lung in association with total CPB may provide important insight into this phenomenon.

Supported in part by grant RR-01032 from the General Clinical Research Centers Program of the Division of Research Resources, National Institutes of Health.

Radioimmunoassay analyses were performed by Janet Hurwitz.

We wish to thank Bernard J. Ransil, MD, PhD, Director of the Core Laboratory and Biostatistician for the General Clinical Research Center, for his advice and assistance in analyzing these data. We also thank Mr Alvin Franklin for his excellent technical assistance.

Cavopulmonary Connection in Repair of Atrioventricular Septal Defect With Small Right Ventricle

Oswaldo Alvarado, MD, Narayanswami Sreeram, MRCP, Roxane McKay, MD, and Isobel M. Boyd, FFARCS

Cardiac Unit, Royal Liverpool Children's Hospital, Liverpool, England

Between February 1991 and May 1992, 9 patients with a nonrestrictive inlet ventricular septal defect or complete atrioventricular septal defect and hypoplasia of the right ventricle underwent successful two-ventricle correction incorporating a bidirectional cavopulmonary anastomosis. Despite a satisfactory early postoperative course, large serous pleural effusions developed in 5 of them between 2 and 6 weeks after operation. Serial echocardiography showed an evolution of flow patterns in the superior vena cava from marked systolic reversal imme-

diately after operation to nearly continuous forward flow into both pulmonary arteries about 6 weeks later. This pattern was consistent with the transition from cardiac-dependent to respiratory-dependent caval flow. The development of pleural effusions appeared to coincide with the loss of systolic caval flow reversal and resolved after establishment of a predominantly respiratory-dependent flow pattern.

(*Ann Thorac Surg* 1993;55:729-36)

Although more common when there is associated right ventricular outflow obstruction [1], hypoplasia of the right ventricle occurs infrequently in the presence of a complete atrioventricular (AV) septal defect with nonrestrictive interventricular communication [2]. Such patients are theoretically candidates for a Fontan type of operation [3] but often have associated incompetence of a common AV valve or suboptimal pulmonary vasculature for this procedure. The bidirectional cavopulmonary anastomosis (superior vena cava anastomosed end-to-side to the undivided pulmonary artery) has facilitated biventricular repair in patients with pulmonary atresia, intact ventricular septum, and hypoplasia of the right ventricle [4]. Herein, we describe the successful extension of this concept to 9 patients in whom the right ventricle was thought to be inadequate to support the pulmonary circulation after closure of a large interventricular communication.

Material and Methods

Patient Population

Nine patients ranging in age from 4 to 13 years (median age, 5.5 years) underwent repair of right ventricular outflow tract obstruction, closure of atrial and ventricular septal defects, and bidirectional cavopulmonary anastomosis between February 1991 and May 1992 (Table 1). Palliation had previously been accomplished in 4 patients with one or more systemic-pulmonary artery shunts, in 1

patient by balloon dilation of the right ventricular outflow tract [5], and in another patient by both balloon dilation and a systemic to pulmonary artery shunt. The primary diagnosis was complete AV septal defect combined with tetralogy of Fallot (4 patients), double-outlet right ventricle (2), pulmonary stenosis (1 patient), or extreme left ventricular dominance (1). The final patient, a boy aged 4.5 years, had a large inlet ventricular septal defect of the AV canal type, a secundum atrial septal defect, and infundibular and valvular pulmonary stenosis with bilateral superior venae cavae. Two children had a left superior vena cava draining to the left-sided atrium, and in 1 child, there was right atrial isomerism. Down's syndrome was present in 5 patients.

The cardiac malformation was investigated by preoperative echocardiography, cardiac catheterization, and angiography. All 8 patients with complete AV septal defect had mild or moderate left AV valve regurgitation, a finding based on the area and extension of the regurgitant jet into the left atrium using color Doppler ultrasound [6, 7]. Based on its angiographic appearance, the right ventricle was judged preoperatively to be moderately hypoplastic in 7 patients (Fig 1) [8]. In the remaining 2 patients, 1 of whom had double-outlet right ventricle, it was found to be severely hypertrophied with an inadequate cavity volume after insertion of the ventricular septal patch.

In all patients, the diameter of the right AV valve after repair as measured intraoperatively with Hegar's dilators was less than the mean normal value expected from the data of Rowlatt and associates [9] (Table 2). The preoperative right ventricular systolic pressure ranged from 30 to 120 mm Hg (median pressure, 74 mm Hg). The mean pulmonary artery pressure ranged from 10 to 20 mm Hg.

Accepted for publication July 10, 1992.

Fig 1. Right ventricular angiograms demonstrating moderate hypoplasia of the right ventricle: (A) patient 2 (atrioventricular (AV) septal defect with extreme left ventricular dominance); (B) patient 3 (complete AV septal defect with tetralogy of Fallot); and (C) patient 4, (ventricular septal defect).

All preoperative anatomic findings were confirmed at the time of operation. Patients 1, 3, and 5 through 9 had a Rastelli type C AV septal defect, and patient 2 had a Rastelli type A common AV valve (see Table 1) [10].

Surgical Technique

Complete intracardiac repair was carried out through a midline sternotomy with moderate hypothermia (22°C) on cardiopulmonary bypass. Systemic to pulmonary shunts were controlled before the institution of perfusion, and the superior vena cava was cannulated near the innomi-

nate vein to facilitate a cavopulmonary connection. Atrioventricular septal defects were repaired using a two-patch technique with a comma-shaped extension of the Dacron patch to route the left ventricle to the dextroposed aorta [11, 12]. The interatrial communication was closed separately with a patch of autologous pericardium, with the coronary sinus left to drain into the right atrium. The left AV valve was repaired as needed to achieve competence.

Right ventricular outflow obstruction was relieved by a variety of methods including muscle resection, valvot-

Table 2. Surgical Techniques

Patient No.	RVOTO	ASD	VSD	RAVV ^a (mm)	CPA
1	Orthotopic PVR with homograft; PA reconstruction; muscle resection	Large; pericardial patch	Large; Dacron patch	17/27 (-10)	RSVC-RPA
2	None	Very large; pericardial patch	Moderate; Dacron patch	12/21 (-9)	RSVC-RPA
3	Pulmonary valvotomy; muscle resection	Very large; pericardial patch	Large; Dacron patch	16/22 (-6)	RSVC-RPA
4	Pulmonary valvotomy; muscle resection	Large ASD 2; pericardial patch	Large, confluent; Dacron patch	20/22 (-2)	RSVC-RPA; LSVC-LPA
5	Orthotopic PVR with homograft; muscle resection	Very large; pericardial patch	Large; Dacron patch	15/20 (-5)	RSVC-RPA
6	Orthotopic PVR with aortic homograft; muscle resection	Very large; pericardial patch	Large; Dacron patch	15/22 (-7)	RSVC-RPA
7	Pulmonary valvotomy; muscle resection; PA reconstruction	Very large; pericardial patch	Large; Dacron patch	18/20 (-2)	LSVC-LPA
8	Orthotopic PVR with homograft; muscle resection; PA reconstruction	Very large; pericardial patch	Large; Dacron patch	16/20 (-4)	RSVC-RPA
9	Orthotopic PVR with homograft; muscle resection	Very large; pericardial patch	Moderate; Dacron patch	18/22 (-4)	LSVC-LPA; RSVC ligated

^a Data are shown as observed/expected; numbers in parentheses are the standard deviations below mean normal.

ASD = atrial septal defect; ASD 2 = secundum atrial septal defect; CPA = cavopulmonary anastomosis; LPA = left pulmonary artery; LSVC = left superior vena cava; PA = pulmonary artery; PVR = pulmonary valve replacement; RAVV = right atrioventricular valve; RPA = right pulmonary artery; RSVC = right superior vena cava; RVOTO = right ventricular outflow tract obstruction; VSD = ventricular septal defect.

omy, and division of the pulmonary annulus (see Table 2). When this resulted in loss of a competent valvular mechanism, a complete homograft was implanted in the orthotopic position, using the attached branch pulmonary arteries as an onlay patch to relieve bifurcation stenoses as needed [13]. Finally, during rewarming, the cavopulmonary anastomosis was constructed with continuous 7-0 polydioxanone monofilament suture (Ethicon). This was done at the site of any previous aortopulmonary shunt after resection of the Gore-Tex conduit or subclavian artery, or to the upper surface of the pulmonary artery. The azygos or hemiazygos vein, if not previously divided, was ligated.

Results

Five patients had an uncomplicated early postoperative course and were extubated within 48 hours after operation. Four remained ventilator dependent for 7 to 10 days, 3 because of pulmonary infection and 1 because of an intracardiac shunt. The latter patient underwent closure of a residual ventricular septal defect 8 weeks after the original operation and recovered without further complications. An electrocardiogram made at discharge showed normal sinus rhythm in each patient. Medications at

discharge were digoxin, furosemide, and amiloride hydrochloride in standard therapeutic doses.

Large serous pleural effusions developed between 2 and 6 weeks after operation in 5 patients, including the patient with a residual ventricular septal defect. The effusions were bilateral in 1 patient, predominantly left sided in 3, and predominantly right sided in 1. Temporary intercostal drainage was necessary in 4 patients, and all effusions resolved after 4 weeks or less of conservative management.

Follow-up

All patients have been followed up by regular clinical examination and two-dimensional Doppler (pulsed-wave, continuous-wave, and color-flow imaging) echocardiography. The median duration of follow-up is 11 months (range, 1 to 16 months).

Echocardiography

M-mode, two-dimensional, and Doppler echocardiography were performed after operation and at hospital discharge in all patients. In addition, serial follow-up echocardiographic studies were also performed. M-mode echocardiograms of the left ventricle confirmed that the left ventricular ejection fraction was normal for age in all

Fig 2. Pulsed Doppler echocardiographic recording from the superior vena cava 2 days after operation. There is a marked high-velocity flow reversal corresponding to ventricular systole (arrow).

Fig 4. Pulsed Doppler recording of superior vena caval flow 1 month after operation. There is nearly continuous forward flow to the lung, with a brief cessation in flow (arrow) corresponding to peak expiration.

patients. At the time of hospital discharge, 1 patient had a small residual shunt at the ventricular level with a high velocity of transeptal flow on continuous-wave Doppler examination, suggesting a low right ventricular systolic pressure [14]. All 8 patients who had repair of an AV septal defect showed a mild degree of left AV valve regurgitation on Doppler color-flow imaging. None of the patients had evidence of major residual right ventricular outflow tract obstruction. Detailed pulsed Doppler examination of the flow patterns within the superior vena cava, right AV valve, and main and branch pulmonary arteries was performed using a combination of parasternal and suprasternal scan positions.

Four distinct patterns of flow in the superior vena cava were demonstrated, depending largely on the interval from operation. In the immediate postoperative period, there was a marked reversal of flow corresponding to ventricular systole (Fig 2). This systolic reversed flow often exceeded diastolic forward flow into the pulmonary artery both in peak velocity and duration. Approximately 2 weeks after operation, the systolic flow reversal became less marked and occurred only in early systole (Fig 3). In

2 patients, the systolic flow reversal was no longer present 6 weeks later. Instead there was a complete cessation of flow within the superior vena cava immediately after ventricular systole in 1, and in the other, low-velocity forward flow into the pulmonary artery was observed occurring throughout the cardiac cycle, with a brief cessation of flow at peak expiration (Fig 4).

In all patients, the right AV valve inflow pattern was abnormal initially, with the late filling peak ("A" peak, corresponding to atrial systole) being of higher velocity than the early ("E") filling peak. This pattern was not evident in 6 of the 9 patients at the most recent follow-up. In these 6, the velocity of the early filling peak had become equal to or exceeded that of the late peak.

In the early postoperative period (up to 2 weeks after operation), interrogation of flow patterns in the main pulmonary artery just distal to the pulmonary valve showed atrial augmentation of pulmonary flow [15], with early filling of the main pulmonary artery corresponding to atrial systole (Fig 5). This phenomenon also had disappeared within 6 to 8 weeks after repair in all patients.

Initially, the right pulmonary artery distal to the cavo-

Fig 3. Pulsed Doppler recording from the superior vena cava 2 weeks after operation. Systolic flow reversal (arrow) is markedly less prominent and of shorter duration.

Fig 5. Pulsed Doppler recording in the main pulmonary artery, just distal to the pulmonary valve, 1 week after repair. There is a biphasic pattern of flow, with the earlier peak (arrow) corresponding to atrial systole.

Fig 6. Pulsed Doppler recording in the distal right pulmonary artery 2 weeks after repair. There is a high-velocity peak corresponding to ventricular systole (S), and a lower-velocity diastolic flow (D) from the superior vena cava. In contrast, the left pulmonary artery demonstrated only systolic flow.

pulmonary connection demonstrated a biphasic pattern of flow, with a higher-velocity peak corresponding to ventricular systole and a lower-velocity diastolic flow from the superior vena cava (Fig 6). In contrast, the main pulmonary artery, left pulmonary artery, and right pulmonary artery proximal to the cavopulmonary connection showed a monophasic systolic flow peak. At the most recent follow-up, a diastolic contribution to flow from the superior vena cava was evident in both the right and left pulmonary arteries in all patients. These various flow patterns are summarized in Table 3.

Comment

Although less obvious than hypoplasia of the left ventricle, there are several situations in which the right ventricle may be inadequate to convey the entire cardiac output to the pulmonary circulation after closure of a large inter-ventricular communication. In complete AV septal defect with tetralogy of Fallot, about 42% of postmortem specimens have been found to have anatomically smaller than normal right ventricles [1]. This was true of all 6 patients with Fallot's tetralogy or pulmonary stenosis in this series. In addition to a morphologically small chamber, the ventricle can be functionally restrictive as the result of

muscle hypertrophy and reduced compliance, which may be further exacerbated by cardiopulmonary bypass. Such factors generally improve after relief of outflow obstruction but still contribute important limitations to right ventricular performance in the early postoperative period. A ventricle that might otherwise have been adequate also may become compromised by the position of the patch inserted for closure of the ventricular septal defect. In both of our patients with double-outlet right ventricle, the Dacron extension connecting the left ventricle to the aorta occupied a substantial portion of the right ventricular chamber.

Although good results have been achieved with surgical correction of the balanced forms of complete AV septal defect with tetralogy of Fallot [3, 12] or other associated anomalies [11], patients with severe ventricular dominance continue to have a high early and late mortality [2]. In our experience, this outcome usually becomes manifest a few days after operation as progressive right ventricular failure leading to multiorgan dysfunction. Even though a competent pulmonary valve is ensured by implantation of an orthotopic pulmonary homograft, 10% to 15% of such patients eventually die of sepsis, fluid retention, or renal failure.

The Fontan operation is an option for patients with extreme left ventricular dominance [3], but clinical and experimental studies [8, 16] of other malformations have demonstrated improved functional results when the hypoplastic right ventricle is incorporated into the subpulmonary circulation. In tricuspid atresia, this has resulted in a lower right atrial pressure and improved left ventricular ejection fraction [17]. Cardiac output is thought to be enhanced by improved left ventricular filling and augmentation of left ventricular systolic function [18, 19]. Although the volume of right ventricle needed to contribute positive stroke work is uncertain, some data suggest that this should be approximately 30% of normal [16, 20]. Thus in patient 2, in preference to ventricular exclusion or total cavopulmonary connection, the hemodynamic contribution of the small right ventricle (see Fig 1A) was conserved by repair of the AV septal defect.

The minimum right ventricular size that is necessary to accommodate the entire systemic venous return is less well characterized. Two classifications of ventricular size

Table 3. Summary of Evolution of Flow Patterns by Doppler Echocardiography

Time of Pattern	SVC Flow	Pulmonary Flow	RAVV Flow
Immediately postop	Prominent systolic reversal	Atrial augmentation in MPA; biphasic flow in distal RPA only	"A" peak greater than "E" peak (poor RV compliance)
2 weeks postop	Less marked systolic reversal	...	...
6 to 8 weeks postop	No reversal, but complete cessation in systole	...	...
Most recent	Nearly continuous forward flow with brief cessation at end-expiration (respiratory dependent)	Continuous systolic and diastolic flow in RPA and LPA	"E" peak equal to or greater than "A" peak (improved RV compliance)

"A" peak = late filling peak corresponding to atrial systole; "E" peak = early filling peak; LPA = left pulmonary artery; MPA = main pulmonary artery; RAVV = right atrioventricular valve; RPA = right pulmonary artery; RV = right ventricular; SVC = superior vena cava.

based on the tripartite approach to right ventricular morphology have evolved from experience in patients with pulmonary atresia and intact ventricular septum, and are now widely used in surgical decision-making [8, 21, 22]. Both endeavor to predict the utility of incorporating a small right ventricle into the final repair and use the tricuspid valve diameter as an indirect index of right ventricular cavity size. Applying either classification to patients in this series, we found that all hearts had postrepair right AV valve diameters that were at least two standard deviations below the mean normal expected value for body surface area (see Table 2), and all had subjectively moderate to severe hypoplasia of the right ventricle. Consequently, when these findings were confirmed at the conclusion of the intracardiac repair, a bidirectional cavopulmonary anastomosis was performed to reduce the volume load on the right ventricle. In the only patient with a nearly adequate right ventricle and a borderline right AV valve ($z = -2$) (patient 7), a further incentive to use the cavopulmonary connection was the presence of a left superior vena cava draining to the left atrium.

Although only 1 patient has undergone cardiac catheterization postoperatively, echocardiography demonstrated several interesting and important hemodynamic details. Right ventricular compliance immediately after operation was clearly impaired as evidenced by an abnormal pattern of right AV valve inflow, with ventricular filling dependent to a greater degree on atrial systole and with an atrial contribution to pulmonary flow. The right ventricle, however, was capable of useful pump function from the outset, and Doppler recording of pulmonary artery flow showed a dominant systolic filling peak. The atrial contribution to pulmonary flow disappeared within 4 to 6 weeks postoperatively without any apparent change in right ventricular size, again suggesting improved right ventricular compliance with time, enabling the ventricle to better accommodate systemic venous return from the inferior vena cava.

We are not aware of any previous characterization of flow patterns in the superior vena cava or pulmonary arteries after a bidirectional cavopulmonary anastomosis in which the right ventricle also contributes to filling of the pulmonary arteries through the pulmonary valve [23]. In the majority of reported series, either antegrade blood flow through the pulmonary valve is minor or the proximal pulmonary artery has been divided as part of the procedure. As expected, a high degree of venous distensibility enabled the superior vena cava to rapidly accommodate systolic flow from the right ventricle in the immediate postoperative period. With time, there probably was an improvement in compliance of the pulmonary-vascular bed and left ventricle. Thus, with increasing interval from operation, there occurred a marked decrease in the duration and peak velocity of systolic reversed flow in the vena cava and eventually nearly continuous forward flow into the pulmonary artery. This confirms that the previously demonstrated respiratory dependence of pulmonary blood flow after the total cavopulmonary connection [24, 25] may still be operative in these patients, despite the

right ventricular contribution of pulsatile flow during ventricular systole. Perfusion studies have demonstrated that the bidirectional cavopulmonary anastomosis in isolation favors superior vena caval blood flow into the right lung [23]. When there is added forward flow into the pulmonary arteries from the right ventricle, there initially appears to be no contribution at all from the cavopulmonary anastomosis to the perfusion of the left lung, as shown by a complete absence of diastolic flow in the left pulmonary artery. However, continuous diastolic flow to both lungs eventually developed in all patients.

Although the etiology of serous effusions after a Fontan procedure remains obscure, the pathogenesis of late-onset pleural drainage among the patients in this series probably reflects an even more complex interaction of physiological variables. Pulsatile blood flow is known to facilitate movement of interstitial fluid and lymph [26], and formation of pleural fluid may depend, in part, on the systemic venous pressure (to which the parietal pleura and thoracic duct drain) and pulmonary venous pressure (which receives the visceral pleural drainage). Plasma atrial natriuretic peptide has also been implicated in the formation of pleural effusions after total cavopulmonary connection [27]. It is possibly some imbalance of these homeostatic mechanisms during ventricular recovery and the hemodynamic evolution of the pulmonary circulation that lead to the formation of pleural effusions in some of these patients.

In conclusion, the combination of intracardiac repair of a large ventricular septal defect with concomitant bidirectional cavopulmonary anastomosis retains the advantages of a functional ventricle in the subpulmonary circulation and simultaneously reduces volume overload of a hypoplastic right ventricle. In patients with small or hypertrophied right ventricles for whom higher than normal right ventricular pressures and diminished compliance can be expected, these factors may prevent the onset of insidious right ventricular failure in the early postoperative period. However, as ventricular function improves, and for reasons that are not clear, there is a high likelihood of transient pleural effusions developing. The long-term consequences of this unusual pulmonary circulation, particularly in regard to the development of arteriovenous malformations, are also unknown.

Biomechanical Study of Sternal Closure Techniques

Wen Cheng, MD, Duke E. Cameron, MD, Karen E. Warden, PhD,
James D. Fonger, MD, and Vincent L. Gott, MD

Division of Cardiac Surgery, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Median sternotomy is the most commonly used incision in cardiothoracic surgery. Closure of this incision is usually performed with parasternal wires, but alternate techniques have been proposed to improve closure stability. This study compares biomechanical stability of standard wire (No. 5 stainless steel) with that of three types of band closure: 5-mm Mersilene ribbon, 5-mm stainless steel band, and 5-mm plastic band. Eight bisected cadaver sterna were reapproximated using each method of sternal fixation and tested for biomechanical stability using an MTS Bionix 858 Biomechanical Tester. Loads of 50, 100, 150, and 200 Newtons (1 Newton = 1 kg · m/s²) were applied as a distracting force across the closure. A linear regression line of displacement as a function of increasing load was determined for each closure method; the slope of this line is inversely proportional to fixation stability. Displacement and load

correlated linearly for each closure ($r = 0.99$). Mean slopes were 0.012 mm/Newton (95% confidence limits, 0.0098 to 0.0142 mm/Newton) for No. 5 stainless steel wire, 0.014 mm/Newton (95% confidence limits, 0.0118 to 0.0162 mm/Newton) for plastic band, 0.017 mm/Newton (95% confidence limits, 0.0148 to 0.0192 mm/Newton) for Mersilene ribbon, and 0.017 mm/Newton (95% confidence limits, 0.0148 to 0.0192 mm/Newton) for 5-mm steel band. No. 5 stainless steel wire provided the most stable closure, although statistical significance was achieved only in comparison with Mersilene ribbon and stainless steel band ($p < 0.05$). The superior stability of stainless steel wire closure may be due to tightening of the wires by twisting, which results in more tension across the reapproximated sternal halves than with other methods.

(*Ann Thorac Surg* 1993;55:737-40)

The median sternotomy, first popularized by Julian and co-workers in 1957 [1], has become the most commonly used incision in cardiothoracic surgery. Although closure of this incision is usually simple and straightforward, healing complications such as instability, non-union, and infection still occur in 0.4% to 5% of cardiac surgical patients [2-8]. Furthermore, widespread use of the internal mammary artery graft for coronary revascularization and the growing proportion of reoperative procedures have contributed to further increases in the incidence of sternal complications [3] and have raised interest in the optimal method of sternal closure.

Closure of the median sternotomy incision is usually performed with parasternal wires, but alternate techniques have been devised to improve closure stability. These alternate techniques attempt to redistribute tension across the incision by banding or by complex wiring techniques [9-20]. However, few studies have attempted to quantitate the degree of fixation achieved by these different approaches.

In orthopedic surgery, different methods of bony fixation have been compared in various models by measuring displacement of the bony structures when subjected to increasing load. The slope of displacement over load is "stiffness" and is a measure of fixation stability. A stiffer

repair has less displacement at each load and is more stable. Typically, a biomechanical tester is used to apply increasing load to a repair; displacement is measured with a strain gauge. Employing a biomechanical tester, we compared the stability of simple No. 5 stainless steel wire closure with that of 5-mm Mersilene ribbon (woven polyester suture; Ethicon Laboratories, Somerville, NJ), 5-mm plastic band (Panduit Corporation, New Lenox, IL), and 5-mm steel band closure (Panduit Corporation) (Fig 1).

Material and Methods

Study Protocol

Eight cadaver sterna were removed en bloc with approximately 10 cm of rib length on each side of ribs two through six. Median sternotomies were performed with an oscillating saw. Each sternum was prepared for mechanical testing in the following manner: Steinman pins were drilled through each rib and the ribs then potted in a rectangular steel mold filled with adhesive (Fig 2). The mold was designed for the jig of an MTS Bionix 858 Universal Biomechanical Tester. An initial loading test was performed on one sternum fixed with No. 5 stainless steel wire. The sternum was tested in tension, with the load applied as a distracting force across the closure at a rate of 1.25 mm/s until failure. The recorded load to failure was 650 Newtons (1 Newton = 1 kg · m/s²). Subsequent testing was performed at loads well below this failure load to stay within the elastic range of the specimen.

Four methods of sternal fixation were studied: No. 5

Fig 1. Materials used in sternal closure (top to bottom) No. 5 stainless steel wire, 5-mm Mersilene ribbon, 5-mm steel band, and 5-mm plastic band.

stainless steel wire, 5-mm plastic band, 5-mm Mersilene ribbon, and 5-mm steel band. Each was tested in random sequence on every sternum. Testing consisted of repetitive loading for 100 three-second cycles with four different loads: 50, 100, 150, and 200 Newtons. The average displacement, as measured by a strain gauge between cycles 10 to 100, was the displacement for that particular load.

The four methods of closure were compared based on the change in displacement with increasing loads. Regression analysis yielded a least-squares estimate of slope of displacement versus load. Repeated-measures analysis of variance was performed to compare the slopes of displacement versus load for each method. Mean and 95% confidence limits (CL) of slope for each method were

calculated and plotted. Methods were considered to be significantly different at p less than 0.05 if the 95% CL did not overlap.

Surgical Technique

Mersilene ribbon is a woven polyester tape 5 mm wide and 30 cm long, swedged on two large blunt needles. It is placed around the lateral border of the sternal body in the intercostal space. A half-knot is placed and the tape is tightened with a clamp placed across the half-knot to avoid slippage before the second knot. Two additional square knots are then placed. The No. 5 stainless steel wire was passed around the sternal body in the intercostal space and tightened with symmetric twisting using a large needle driver. The plastic and steel bands were passed around the sternal body in the intercostal space with a curved clamp, and then threaded through the buckle and secured with an applicator gun.

Results

There was a strong linear correlation between displacement and load for each method tested ($r = 0.99$). The slope of displacement versus load was 0.012 mm/Newton (95% CL, 0.0098 to 0.0142 mm/Newton) for No. 5 stainless steel wire, 0.014 mm/Newton (95% CL, 0.0118 to 0.0162 mm/Newton) for 5-mm plastic band, 0.017 mm/Newton (95% CL, 0.0148 to 0.0192 mm/Newton) for Mersilene ribbon, and 0.017 mm/Newton (95% CL, 0.0148 to 0.0192 mm/Newton) for 5-mm steel band. Pairwise comparisons showed No. 5 stainless steel wire a more stable closure than Mersilene ribbon and steel band ($p < 0.05$), but not statistically better than plastic band. There were no significant differences among plastic band and Mersilene ribbon or steel band.

Comment

Sternal nonhealing and sternal infection are serious complications of median sternotomy and lead to considerable morbidity and mortality [3-5]. Mechanical instability of the closure is an important factor contributing to both nonhealing and infection. Previous studies have documented that prolonged cardiopulmonary bypass, excessive postoperative bleeding, depressed cardiac output, reexploration for hemorrhage, and use of the internal mammary artery graft also predispose to healing compli-

Fig 2. Sample sternum secured in mold for testing in MTS Biomechanical tester. Depicted sternum has been closed with No. 5 stainless steel wire.

Fig 3. Relationship of stress and strain.

cations [2-8], but inadequate mechanical stabilization of the sternum is undoubtedly an important variable, although difficult to identify and quantitate. Because of the high morbidity and mortality attending sternal complications, there is interest in alternate methods of sternal fixation [9-20].

There are theoretic advantages of banding techniques over wire closure for sternal fixation. By spreading load over a larger surface area, the applied stress (force/area) is less. A band repair may exhibit less displacement with a given load and be stiffer. Moreover, at equivalent loads, a band should be less likely to break or cut into the sternum. Therefore, we chose to compare standard wire closure with three types of band closure: 5-mm Mersilene ribbon tape, 5-mm plastic band, and 5-mm stainless steel band.

Because of the unique shape of the human sternum, use of cadaver specimens is the best model to assess sternal closure stability. The configuration that a band or wire assumes around the sternum influences the way in which tension is applied to the sternum and thus affects stability. Moreover, due to the wide variability in stiffness among sterna, each fixation technique must be randomly tested on each specimen.

Each cadaver specimen subjected to tensile loading has a characteristic stress-strain curve (Fig 3). On the stress-strain curve, the initial straight line represents elastic behavior. Elastic behavior is characterized by full recovery from deformation, ie, a force will deform the material, but on removal of the force the material will regain its original dimensions. There is a linear relation between force and deformation, with each unit of force producing the same increment in deformation. The yield point is the point on the curve where an increase in strain or deformation occurs without significant increase in stress or load. Beyond the yield point, the material deforms with plastic

behavior; any strain developed along this portion of the curve results in permanent change of the material. To stay within the elastic range of the specimen it is important to stay well below the yield point.

Initial tensile loading tests indicated a yield point of about 650 Newtons for a representative human sternum. Therefore we elected to use 50-Newton increments between 50 and 200 Newtons. One hundred 3-second cycles were applied for each test to mimic movement associated with ventilation. Average displacement was compared with load from cycles 10 to 100.

In this model of sternal fixation, using a biomechanical tester to compare repair stability, we were unable to document an advantage of a band-type repair over standard steel wire closure. In fact, under these conditions, No. 5 stainless steel wire proved superior to steel band and Mersilene ribbon. At loads within the elastic range of sternal deformation, stainless steel wire fixation resulted in less sternal motion than either Mersilene ribbon or steel band. The advantages of steel wire fixation over Mersilene ribbon appear to be due to the fact that steel is stiffer than Mersilene and the symmetric twist closure is superior to knot fixation in maintaining tension across the sternal halves. A consistent, reproducible amount of tension can be applied and maintained in cerclage wiring by twist fixation [21, 22]. In contrast, during tying, tension must be released for the second half-knot to be tied. The advantage of steel wire over steel band may also result from its superior ability to conform to the shape of the sternum. Steel band was designed to fit circular objects such as pipes, but its prominent buckle hinders a secure fit around the sternum.

When compared with plastic band closure, steel wire closure was more stable, although this difference did not reach statistical significance because of the limited number of specimens. The plastic band conforms better to the sternum because of its less prominent buckle and superior malleability.

As is commonly accepted in orthopedic surgery, we assume that more stable bony fixation leads to better healing in sternal closure. Undoubtedly, other factors such as bacterial contamination, sternal ischemia, diabetes, and unusual disrupting forces (violent coughing) also contribute to healing problems, but many of these are beyond the control of the cardiothoracic surgeon. Therefore, additional efforts to improve stabilization in the face of these risk factors is essential.

Encouraged by these experimental results, we continue to use stainless steel wire closure at The Johns Hopkins Hospital despite experience with other methods of closure. In our current practice, we place one or two No. 6 stainless steel wires in the manubrium, followed by "figure-of-8" wires around the sternum between the costal cartilages. We have not compared figure-of-8 closure with simple interrupted sutures in this study, but we believe that figure-of-8 wiring maintains the benefits of cerclage wiring and still allows the force to be displaced over a greater surface area, recruiting the theoretic benefits of banding.

We conclude that standard stainless steel wire closure is

more stable than Mersilene ribbon and steel band when the applied load is within the elastic range of the human sternum. Although a band theoretically should allow less plastic deformation than wire, this advantage is lost if the band cannot maintain tension between the sternal halves because of poor fit. Wire closure remains the standard against which alternate fixation methods should be compared. Finally, this study suggests that new methods of sternal fixation can be evaluated in vitro with biomechanical testing methods before clinical use.

Pulmonary Artery Balloon Counterpulsation: Safe After Peripheral Placement

George V. Letsou, MD, Kenneth L. Franco, MD, Wayne Detmer, BA, Spyros Condos, MS, Sidney Wolvek, MA, G. J. Walker Smith, MD, and John C. Baldwin, MD

Section of Cardiothoracic Surgery and Department of Pathology, Yale University and Yale-New Haven Hospital, New Haven, Connecticut, and Datascope, Inc, Oakland, New Jersey

Pulmonary artery balloon counterpulsation is a promising experimental technique for treatment of right ventricular failure. However, clinical application has been limited in that the only device presently available (the large-volume intraaortic balloon) must be placed within a synthetic graft. Because a balloon with a smaller volume (which could be placed through a peripheral vein and be contained entirely within the pulmonary artery) would make the technique feasible on a wider scale, we tested an 8-mL pulmonary artery balloon placed through the femoral vein in 12 dogs. Two groups of animals were compared. One group had the pulmonary artery balloon in place but not counterpulsating; the other had the pulmonary artery balloon in place and counterpulsating. Each group was studied for 12 hours. A variety of hemodynamic parameters were measured. Effective dia-

stolic augmentation and systolic unloading were noted in all 6 dogs that underwent counterpulsation (5.0 ± 1.1 mm Hg of diastolic augmentation and 9.5 ± 1.6 mm Hg of systolic unloading). Pulmonary function, as measured by arterial blood gas sampling and pulmonary vascular resistance, was not impaired. Examination of the heart and lungs showed no detrimental pathologic effects of pulmonary artery balloon counterpulsation. Placement of the balloon through a peripheral vein with a guidewire was easy and uncomplicated. We conclude that pulmonary artery balloon counterpulsation is safe over an extended period of 12 hours in the canine model and that diastolic augmentation and systolic unloading can be produced.

(*Ann Thorac Surg* 1993;55:741-6)

Pulmonary artery balloon counterpulsation (PABC) is a promising technique for treatment of right ventricular failure. The technique has produced dramatic improvement in sporadic clinical cases of right ventricular failure [1-3]. In such cases, a standard intraaortic balloon pump has been inserted into a synthetic vascular graft anastomosed in an end-to-side fashion to the pulmonary artery; complete recovery from right ventricular failure has been reported. Animal studies have also shown PABC to ameliorate experimentally induced right ventricular failure over the short term (ie, less than 1 hour) [4-6]. However, the requirement for sternotomy has limited clinical applicability of PABC.

We developed a device that could be inserted percutaneously through the femoral vein and was small enough to fit entirely within the pulmonary artery. We then tested its hemodynamic efficacy and safety over an extended period of 12 hours.

Material and Methods

Adult mongrel dogs weighing 20 to 30 kg were fully anesthetized using pentobarbital (20 mg/kg) and halo-

thane (0.5% to 1.5%). A volume ventilator (Harvard Apparatus Company, Inc, Millis, MA) was used to administer both inhalational anesthetic agents and oxygen. Lactated Ringer's solution or normal saline solution was administered intravenously to maintain a urine output of 0.5 to $1.0 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ and a central venous pressure of 1 to 5 mm Hg.

The pulmonary artery balloon device inserted was manufactured by Datascope, Inc (Oakland, NJ). It had an 8-mL capacity, a 16-mm proximal diameter (tapering gradually to its distal insertion on a 9.5F catheter), and a length of 55 mm. This device provided the most appropriate dimensions in our canine model. (Other devices with volumes of 10.5 and 20 mL and proximal diameters of 17 and 19 mm, respectively, required excessive amounts of pressure to fill completely in preliminary trials.)

Animals were divided randomly into two groups. The first group consisted of 6 control animals. In these animals, an arterial cannula was placed in the right femoral artery for blood pressure monitoring and arterial blood gas sampling. The right femoral vein was used for both central venous pressure monitoring and volume infusion. The right external jugular vein was isolated, and a pulmonary artery catheter (American Edwards Laboratories, Irvine, CA) was passed into the pulmonary artery. This catheter was used to monitor pulmonary artery pressures,

Accepted for publication July 13, 1992.

pulmonary capillary wedge pressure, and cardiac output (by the thermodilution technique). The left femoral vein was exposed for subsequent introduction of the PABC device. A right anterolateral thoracotomy was performed through the fourth intercostal space. After the pericardium was opened, a catheter was inserted through the anterior wall of the right ventricle into the right ventricular cavity for measurement of right ventricular pressures and the positive and negative first derivative of right ventricular pressure (RV dP/dt). After insertion of a 28-gauge chest tube through a separate stab wound incision, the thoracotomy was closed. A suprapubic cystostomy allowed hourly determination of urine output. All animals were given heparin to maintain an activated clotting time of greater than twice control.

The deflated PABC device was positioned in the pulmonary artery as described below. Baseline hemodynamic parameters including heart rate, arterial pressure, central venous pressure, right ventricular pressure, pulmonary artery pressures, pulmonary capillary wedge pressure, cardiac output, positive RV dP/dt, and negative RV dP/dt were recorded. Under baseline conditions, arterial blood gases were measured and blood samples were analyzed for determination of creatine kinase level. A serum sample was also obtained for liver function tests and measurement of electrolytes, blood urea nitrogen, and creatinine levels. Anesthesia was continued for 12 hours, during which time hourly determinations of hemodynamic parameters were made. Arterial blood gases were monitored hourly and appropriate changes in ventilator rate were made. Serum samples for liver function tests and measurement of cardiac enzymes, electrolytes, blood urea nitrogen, and creatinine were obtained at 6 and 12 hours. After 12 hours of continuous monitoring, control animals were sacrificed using an overdose of pentobarbital and potassium chloride as per the Yale Animal Care and Use Committee protocols. The heart and lungs were excised as a block for pathologic examination. Both kidneys and the liver were also removed for pathologic examination. All organs were fixed in a 10% solution of formaldehyde.

The second group of 6 animals underwent 12 hours of PABC. Full hemodynamic monitoring was instituted as in control animals. The left femoral vein was exposed proximally and distally for subsequent introduction of the PABC device. Under fluoroscopic guidance the pulmonary artery was cannulated from the left femoral vein using a second, standard pulmonary artery catheter with a 1-mL balloon. Once in place, a wire was inserted through the central lumen of this pulmonary artery catheter. The catheter was withdrawn, leaving the wire in place. Subsequently, the PABC device was inserted over the wire under fluoroscopic guidance. Radiopaque markers at the tip of the PABC device permitted visualization within the pulmonary artery. The proximal third of the device was positioned in the main pulmonary artery and the distal two thirds in either the right or left pulmonary artery (Fig 1). An injection of Renograffin-76 (diatrizoate meglumine and diatrizoate sodium injection; Squibb Diagnostics, New Brunswick, NJ) was then administered through the central lumen of the PABC device; visualiza-

Fig 1. Position of pulmonary artery balloon counterpulsation device during counterpulsation. Proximal third of balloon is located in main pulmonary artery. Distal two thirds of balloon are located in left or right pulmonary artery.

tion of a branch of the right or left pulmonary artery confirmed appropriate device position.

At right anterolateral thoracotomy, the device was inflated gently and position was confirmed by palpation. A right ventricular catheter for measurement of right ventricular pressure, positive RV dP/dt, and negative RV dP/dt was placed through the right ventricular free wall, and the anterolateral thoracotomy was closed. A suprapubic cystostomy was placed.

Baseline parameters were measured as in the control group of animals. Pulmonary artery balloon counterpulsation was then initiated using a Datascope System 83 drive (Datascope, Inc). An arterial pressure wave form recorded from the distal port of the PABC device was used to time counterpulsation. Balloon inflation began just after pulmonary valve closure as indicated by the dicrotic notch in the pulmonary artery trace, and deflation began just before the following systolic contraction of the heart. Counterpulsation continued for 12 hours. Hemodynamic and serum studies were then obtained as in the control group. At the conclusion of 12 hours of counterpulsation, animals were sacrificed as described above. Heart and lungs were excised as a block for pathologic examination, as were both kidneys and the liver. All organs were fixed in 10% formalin for pathologic examination. At the conclusion of each experiment, the PABC device was withdrawn and examined for clot or damage.

Table 1. Hemodynamic Parameters in Control Animals ($n = 6$) and Experimental Animals ($n = 6$) at 12 Hours

Index	Control (PABC device inserted but not activated) ^a	Experimental (PABC device inserted and activated) ^a	p Value ^b	95% Confidence Limits
Heart rate (beats/min)	142 $\pm$ 8.0	149 $\pm$ 5.0	0.48	-28.9, 14.5
Central venous pressure (mm Hg)	4.0 $\pm$ 2.0	5.5 $\pm$ 1.2	0.65	-6.1, 4.1
Right ventricular end-diastolic pressure (mm Hg)	5.5 $\pm$ 1.7	5.2 $\pm$ 1.3	0.36	-2.7, 6.7
+dP/dt (mm Hg/s)	1,733 $\pm$ 393	1,417 $\pm$ 353	0.60	-1,050, 1,683
-dP/dt (mm Hg/s)	1,433 $\pm$ 384	1,267 $\pm$ 349	0.77	-1,513, 1,180
Cardiac index (L/min $\cdot$ m ²)	4.95 $\pm$ 0.84	4.52 $\pm$ 0.60	0.69	-1.6, 3.1
Pulmonary vascular resistance (Wood units)	3.05 $\pm$ 0.70	2.72 $\pm$ 0.44	0.70	-1.5, 2.2

^a Mean $\pm$ standard error. ^b Two-sample t test.

dP/dt = first time derivative of right ventricular pressure; PABC = pulmonary artery balloon counterpulsation.

All results were indexed using basal surface area as calculated using the equation [7]: canine basal surface area = $0.112 \times 2/3$ body weight in kilograms.

All animals received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985). The Yale University Animal Care and Use Committee also approved and regulated the use of all animals.

All data are presented as mean $\pm$ standard error. The two-sample t test and the paired t test were used to test differences between the groups. A p value of less than 0.01 was considered significant.

Results

All 12 animals completed the protocol without operative death. Data from the 6 control animals were pooled for analysis, as were data from the 6 experimental animals.

Hemodynamic Effects

A comparison of the hemodynamic parameters in the control group after 12 hours with parameters in the experimental group after 12 hours of PABC is presented in Table 1. No difference in heart rate, central venous pressure, right ventricular end-diastolic pressure, positive and negative RV dP/dt, cardiac index, or pulmonary vascular resistance was detected ($p > 0.01$). A second comparison of hemodynamics within the experimental group of animals just after PABC initiation (0 hours) and after 12 hours of PABC revealed no statistically significant differences in any of these hemodynamic parameters at the p less than 0.01 level (Table 2). A third comparison of baseline and 12-hour hemodynamic parameter differences in control and experimental groups using a two-sample t test revealed both groups to be comparable at baseline conditions (Table 3), indicating that the lack of significant changes in hemodynamic parameters at 12 hours was not due to differences between the two groups of animals under baseline conditions.

There was, however, a marked increase in both dia-

Table 2. Hemodynamics in Experimental Animals After Initiation of PABC (0 Hours) and After 12 Hours of PABC ($n = 6$)

stolic augmentation and systolic unloading within the experimental group after 12 hours of PABC as compared with shortly after PABC initiation (0 hours). The amount of diastolic augmentation increased from 0.5 ± 0.5 mm Hg just after PABC initiation to 5.0 ± 1.1 mm Hg after 12 hours ($p < 0.01$). The amount of systolic unloading also increased from 1.5 ± 1.0 mm Hg at PABC initiation to 9.5 ± 1.6 mm Hg after 12 hours of counterpulsation ($p < 0.01$). A typical tracing after 12 hours in the experimental group is shown in Figure 2. It should be noted that pulmonary vascular resistance did not change significantly over the same period.

Arterial Blood Gas Analysis

No detrimental effects on pulmonary function as determined by arterial blood gas analysis were noted. The pH in the control group (7.39 ± 0.02) was not significantly different than that in the experimental group (7.32 ± 0.02) after 12 hours ($p > 0.01$). Nor were carbon dioxide tension or oxygen tension different ($p > 0.01$) in the control group as compared with the experimental group of animals after 12 hours (29 ± 2.8 versus 31 ± 2.6 mm Hg and 327 ± 39 mm Hg versus 415 ± 39 mm Hg, respectively). Within the experimental group there were no significant differences ($p > 0.01$) noted between the pH, carbon dioxide tension, or oxygen tension at 0 or 12 hours (Table 4). (Although changes in ventilation were made as the exper-

iment progressed, no animal required a ventilatory rate greater than 10 breaths per minute; oxygenation was always with an inspired oxygen fraction of 0.40.)

Serum Analysis for Creatine Kinase, Renal Function, and Liver Function

Creatine kinase levels and liver function test results (including levels of alkaline phosphatase, serum glutamic-oxaloacetic transaminase, total bilirubin, and indirect bilirubin) were obtained at 6 and 12 hours in 3 control animals and 5 experimental animals (Veterinary Labs of America, Lindenhurst, NY). None showed an increase in the MB fraction of creatine kinase. Blood urea nitrogen and creatinine levels were normal in all animals. Alkaline phosphatase and serum glutamic-oxaloacetic transaminase levels were frequently elevated in both control and experimental animals. Total bilirubin and indirect bilirubin levels were normal in all animals.

Pathology

At the conclusion of each experiment the liver, both kidneys, and the heart-lung block were excised for pathologic examination. Gross examination revealed no obvious pathologic structural abnormalities of any organ. Sectioning of the heart-lung blocks revealed all except one to be without abnormalities attributable to the PABC device. One animal, in which the balloon leaked on

Fig 3. Pathologic specimens from both control and experimental animals. (A) Pulmonary artery from a control animal. There is no evidence of thrombus or endothelial damage. The media is normal. (Hematoxylin and eosin, $\times 100$ before 47% reduction.) (B) Pulmonary artery in region of contact with balloon from an experimental animal. Red blood cells within a fine fibrin mesh are adherent to the endothelial surface at right of photomicrograph. The media of the vessel is undamaged. (Hematoxylin and eosin, $\times 100$ before 48% reduction.)

manipulation of the pulmonary artery just after the experiment's conclusion (to obtain specimens for pathologic analysis), had gross hemorrhage of the right main pulmonary artery adventitia.

Microscopic examination of the pulmonary arteries was unremarkable in all cases except for the 1 animal in which the balloon ruptured after the experiment's conclusion. Minimal aggregation and adherence of various blood cells to pulmonary artery endothelium occurred. None of the microscopic findings were clinically significant. Evidence of endothelial damage or erosion was absent microscopically. A typical microscopic section from a control animal is compared with that of an experimental animal in Figure 3. Thrombosis within the pulmonary vasculature surrounded by an old bronchopneumonia was found in 1 animal but was not related to the PABC device. No other pulmonary thrombi were found.

Pulmonary artery balloon counterpulsation devices removed at the conclusion of each experiment were carefully examined for any evidence of clot or thrombus formation, and no such evidence was found.

Comment

Pulmonary artery balloon counterpulsation has been effective in several experimental models [4]. As early as 1970, Kralios and associates [5] demonstrated the efficacy of PABC in sheep using a 25-mL balloon. In a model of right ventricular failure caused by corn starch embolization, cardiac output increased and pulmonary vascular resistance decreased with PABC. This report was followed by one from Spotnitz and associates [6] using a piston pump for counterpulsation of the pulmonary artery in dogs. Their short-term experiment (10 minutes) showed that synchronized counterpulsation significantly reduced peak right ventricular systolic pressure in normal dogs and in dogs with pulmonary hypertension produced by pulmonary artery constriction. Miller and associates [1] reported the first clinical use of a system for PABC in 1980. They employed a synthetic vascular graft sutured to the main pulmonary artery in an end-to-side fashion as a reservoir for a 35-mL balloon. This method of PABC was used in tandem with an intraaortic balloon to ameliorate severe biventricular failure after coronary artery bypass grafting. Significant hemodynamic improvement occurred, although the patient eventually died. Using a similar system, Flege and colleagues [2] reported the first successful use of PABC for severe right ventricular failure after mitral valve replacement. The technique was unwieldy, however, and has not been widely accepted or used.

Several other authors have shown PABC to be effective in short-term models. Pulmonary artery balloon counterpulsation is effective in increasing right ventricular output in swine with right ventricular failure induced by propranolol while the left heart is supported on left heart bypass [8]. Cardiac output increased from 0.4 to 0.7 L/min in this model. Another model in swine showed the efficacy of 40 minutes of PABC in right ventricular failure produced by right ventriculotomy; right ventricular end-diastolic pressure decreased 50% and cardiac output increased by 44% [9]. A longer term experiment performed by Jett and associates [10, 11] in lambs revealed increased cardiac output, decreased right ventricular peak systolic pressure, and decreased right ventricular end-diastolic pressure with counterpulsation.

With such experimental and clinical evidence for the effectiveness of PABC, a question of primary importance is whether the technique can be adapted for easy and safe clinical use. Our objective in developing and testing the 8-mL PABC device was to demonstrate its ease of use, safety, and hemodynamic efficacy.

Unlike previous devices used for PABC, this one, with its smaller catheter caliber (similar to the widely used intraaortic balloon), was easily inserted through the femoral vein into the pulmonary artery in all animals. The technique is similar to insertion of a pulmonary artery

catheter, although device rigidity makes placement under fluoroscopic guidance mandatory. Device position was easily confirmed with injection of radiopaque material through the central port of the catheter. Once in place, the balloon did not migrate proximally or distally in any of our experiments. Ventricular ectopy was not significant, although occasional premature ventricular contractions were noted.

Diastolic augmentation and systolic unloading were minimal just after initiation of counterpulsation. This is not unexpected; intraaortic balloon counterpulsation also produces minimal effects in normal animals, and similar findings have been reported in pulmonary artery counterpulsation [6]. Nevertheless, diastolic augmentation and systolic unloading increased over time and were statistically significant at 12 hours. Previous animal studies have not addressed this phenomenon, as most were of much shorter duration. Obviously, future studies must address the question of whether PABC can ameliorate or reverse experimentally induced right ventricular failure.

We selected a balloon size of 8 mL for our 25- to 35-kg animals. Although others have used balloons as large as 25 mL in pigs [12], our preliminary investigations using balloons of larger size frequently resulted in right ventricular outflow tract obstruction with subsequent right ventricular dilation and failure, particularly if any mistiming of balloon inflation and deflation occurred. The relatively small balloon may be one reason we detected little hemodynamic improvement initially. However, our smaller balloon size minimized the problem of improper timing of inflation or deflation (no episode of right ventricular dilation occurred) and still provided dramatic hemodynamic effects after 12 hours. Placement of the device close to the pulmonary valve is important. In contrast to intraaortic balloon counterpulsation, the pulmonary artery balloon can be placed very close to the ventricular outflow tract, thereby magnifying the effect of a relatively small balloon [13].

Previous reports have suggested that pulmonary vascular thrombosis may be produced by counterpulsation [14]. As prophylaxis against thrombosis, activated clotting time was kept at least twice control values in our series, and pathologic studies revealed no evidence of thrombosis. Balloon position was confirmed with fluoroscopy after placement and was probably important in avoiding pulmonary valve or artery damage. After 12 hours of counterpulsation, no pulmonary valve or pulmonary artery intimal damage occurred in any animal. Although a longer period of 24 to 72 hours of observation would be desirable, considerations concerning the humane care of animals make this impossible at our institution.

Analysis of creatine kinase levels revealed no elevation at 6 or 12 hours in any animal. Arterial blood gas samples revealed no deterioration in oxygenation or ventilation with counterpulsation of 12 hours duration. Thus, no biochemical evidence of cardiopulmonary damage was found after 12 hours of counterpulsation.

In summary, PABC is a promising technique for the treatment of right ventricular failure through afterload reduction. It is possible to achieve diastolic augmentation and systolic unloading after placement of an appropriately sized device through the femoral vein. Counterpulsation is free of detrimental effects on cardiac function after 12 hours. Further studies on a long-term model of right ventricular failure are warranted before widespread clinical use.

We wish to acknowledge the assistance of Terry O'Connor, MA (Department of Anesthesiology, Yale University), in the preparation of the statistical analysis.

Age and Protection of the Ischemic Myocardium: Is Alkaline Cardioplegia Appropriate?

John E. Baker, PhD, Lawrence E. Boerboom, PhD, and Gordon N. Olinger, MD

Department of Cardiothoracic Surgery, Medical College of Wisconsin, Milwaukee, Wisconsin

Hypothermic alkaline pharmacologic cardioplegia used in pediatric cardiac surgery may be less than satisfactory despite its benefits in adults. We determined whether the pH (7.8) of standard St. Thomas' II cardioplegic solution contributes to inadequate protection of the ischemic immature heart and whether the effect is age-related. Modified hypothermic St. Thomas' II solution (pH range, 4.8 to 8.8) was compared with hypothermic bicarbonate buffer alone (pH 7.25) in protecting the ischemic immature (7 to 10 days old) and mature (12 months old) rabbit heart. Isolated hearts ($n = 6$ per group) were perfused with bicarbonate buffer, and aortic flow was measured before hypothermic (14°C) ischemia (immature hearts: 4 hours; mature hearts: 3 hours). Hearts were reperfused, and enzyme leakage and recovery of function were measured. In the immature heart, a bell-shaped dose-response profile was observed for pH and

recovery of aortic flow but not for postischemic creatine kinase leakage. Optimal recovery of aortic flow ($98\% \pm 3\%$) occurred at pH 6.8, which was greater than protection with hypothermia alone ($82\% \pm 4\%$; $p < 0.05$) and standard St. Thomas' II solution ($72\% \pm 2\%$; $p < 0.05$). In the mature heart, a bell-shaped dose-response curve existed for recovery of aortic flow and a U-shaped curve existed for creatine kinase leakage. Again, optimal recovery of aortic flow ($84\% \pm 5\%$), which was superior to that with standard St. Thomas' II solution ($60\% \pm 8\%$; $p < 0.05$), and minimal enzyme leakage also occurred at pH 6.8, as did the least enzyme leakage ($p < 0.05$). The pH of standard St. Thomas' II solution is suboptimal to protect the ischemic immature and mature myocardium, and protection is improved by mild acidification.

(*Ann Thorac Surg* 1993;55:747-55)

Clinical application of hypothermic pharmacologic cardioplegia in pediatric cardiac surgery has been reported to be less than satisfactory [1] despite its well-known benefits in adults [2]. We [3] have shown that protection of the ischemic immature rabbit heart with hypothermic Krebs bicarbonate buffer alone is better than with hypothermic St. Thomas' II cardioplegic solution. This effect is age [3] and species [4] dependent, but it is independent of the oxygen content in the preischemic perfusate [5]. Our experimental finding is of concern, as St. Thomas' II cardioplegic solution is currently in use during pediatric cardiac operations.

We have hypothesized that the existing concentration of one or more of the components of St. Thomas' II solution is less than optimal or even detrimental to the protection of the ischemic immature heart during hypothermic ischemia. The existing calcium concentration of St. Thomas' II solution is one component responsible for inadequate protection of the ischemic immature rabbit heart [6]. However, the greatest difference in the concentration of an individual component between hypothermic Krebs buffer and St. Thomas' II solution is that of pH. The pH of Krebs buffer as determined at 14°C is 7.25, and the

pH of St. Thomas' II solution, 7.8. This value for St. Thomas' II solution was based on theoretical considerations relating to the anticipated development of acidosis during ischemia in the mature heart [7] as well as the alkaline shift of the pK of water with hypothermia [8, 9]. The suggestion that an alkaline pH is best when formulating cardioplegic solutions has been widely adopted by clinicians and investigators. However, we are aware of no studies that confirm whether myocardial protection of either immature or mature myocardium with St. Thomas' II solution is optimal at this alkaline pH, or determine the interaction of pH with the calcium component of this cardioplegic solution.

The objectives of this study therefore were (1) to determine whether the pH of St. Thomas' II solution contributes to inadequate protection of the ischemic immature heart, (2) to determine whether this effect is age-related, (3) to assess the impact of modifying pH on the calcium activity of the cardioplegic solution, and (4) to determine the effect of temperature on the measurement of pH of the coronary perfusates.

Material and Methods

Experimental Animals

Immature New Zealand white rabbits ($n = 69$) aged 7 to 10 days were obtained from a *Pasteurella*-free breeding colony within the Medical College of Wisconsin. Between 6 and 10 kits (young rabbits) were produced per litter. To avoid dehydration, we allowed mature animals free ac-

Coronary flow (mL/min)	8 ± 2	46 ± 9

^a Data are shown as the mean ± the standard deviation pooled from all animals used in the study. ^b There were no significant differences in preischemic control values between experimental groups. With the exception of body weight and mean aortic pressure, all data were derived from isolated hearts.

cess to water and kept immature animals with their mothers until just before the induction of anesthesia. Mature New Zealand white rabbits ($n = 72$) aged 12 months were obtained from a commercial breeder. Data on body weight and heart weight for the two age groups are shown in Table 1. Animals used in this study received humane care in compliance with the "Principles of Laboratory Animal Care" formulated by the National Society for Medical Research and the "Guide for the Care and Use of Laboratory Animals" prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication No. 85-23, revised 1985).

Heparin sodium (150 IU/kg) was administered intraperitoneally before the administration of anesthetics. Anesthesia was induced and maintained with halothane (4.0% and 1.5%, respectively). The chest was opened, and the pericardium was removed. The aorta and inferior vena cava were isolated, and the heart was rapidly excised and placed in ice-cold Krebs-Henseleit bicarbonate buffer. The time from the opening of the chest to the excision of the heart was less than 1 minute.

Perfusion System

The standard isolated working heart preparation (Biomedix, Elm Grove, WI), described initially by Neely and colleagues [10], was modified to provide a physiological work load and temperature suitable for immature and mature rabbits. The preparation has been described in detail previously [3, 4]. Essentially, it is a left heart preparation in which oxygenated Krebs-Henseleit bicarbonate buffer [11] supplemented with glucose enters the cannulated left atrium at a pressure of 6 mm Hg for immature hearts and 9 mm Hg for mature hearts. The perfusate then passes to the left ventricle, from which it is spontaneously ejected through the cannulated aorta against a compliant hydrostatic head of mean pressure of 42 mm Hg for immature hearts and 88 mm Hg for mature hearts. These pressures are physiologic for immature and mature rabbit hearts [3].

Hearts in each test group in which the control hemodynamic performance deviated by one standard deviation or more from the mean values shown in Table 1 were

excluded from the study. This exclusion criterion resulted in rejection of 9 of 69 immature hearts and 12 of 72 mature hearts. Additional hearts were perfused until 6 were available for analysis of function. The hearts and perfusates were kept in temperature-controlled chambers to maintain myocardial temperature at the desired level. During all periods of ischemia, the heart was immersed in ungasped physiological saline solution.

Perfusion Media

The standard perfusion medium used was Krebs-Henseleit bicarbonate buffer [11] (pH 7.41 at 39°C and 7.25 at 14°C when saturated with 95% oxygen and 5% carbon dioxide [12]) in which the calcium content was reduced to 1.8 mmol/L. To this was added glucose (11.1 mmol/L). The cardioplegic solution used was St. Thomas' II solution [13]. Compositions of the individual perfusates are shown in Table 2. Glucose was excluded from all perfusates during hypothermic Langendorff perfusion of the coronary network immediately before and throughout ischemia. The pH of St. Thomas' II solution (normally 7.8) was modified from 4.80 to 8.80 by manual titration using hydrochloric acid/sodium hydroxide. During the preparation of all calcium-containing solutions, precautions were taken to prevent the precipitation of calcium [14] by gassing the solutions with 5% carbon dioxide. Oxygen content of the perfusates was measured using a Lex-O₂-Con fuel cell analyzer (Lexington Instruments, Waltham, MA) calibrated against room air at room temperature. All measurements of pH were made using a Data Tech 14 pH meter (Data Tech Systems Ltd, Victoria, BC, Canada) calibrated with known pH standards at the temperature of the coronary perfusate. The total calcium content of the coronary perfusate was measured using an IL-357 atomic absorption spectrophotometer (Instrumentation Labora-

Perfusion Sequence

pH AND PROTECTION OF THE IMMATURE HEART. The following experiments were performed in a random manner in ten groups of 6 immature hearts each to test the null hypothesis that protection of the ischemic immature rabbit heart is unaffected by the pH of the coronary perfusate. Immediately after aortic cannulation, the hearts were perfused in the Langendorff [15] mode for a 15-minute stabilization period during which the left atrium was cannulated. The hearts were then converted to the working [10] mode for 35 minutes. During this period, control values for aortic and coronary flow rates, heart rate, and electrical activity were recorded under steady-state conditions. This was followed by a single 3-minute period of hypothermic (14°C) coronary perfusion in the Langendorff mode with either Krebs-Henseleit bicarbonate buffer (pH 7.25) or the modified cardioplegic solution (pH varied from 4.8 to 8.8). The 3-minute period of preischemic coronary perfusion was carried out with perfusion pressure fixed at 60% of the mean aortic pressure for the immature rabbit heart. This reduced pressure was selected to minimize the development of iatrogenic myocardial edema while maintaining adequate volume of perfusion and cooling of the heart.

Hearts were then subjected to global hypothermic (14°C) ischemia for 4 hours. This is the target temperature commonly achieved and maintained clinically during cardioplegic arrest of the immature heart [1]. After the ischemic period, hearts were reperfused for 15 minutes in the Langendorff mode with the entire coronary effluent collected for the determination of creatine kinase activity. Hearts were then converted to the working mode for 35 minutes, during which time the various indices of function were measured under steady-state conditions and expressed as a percentage of the preischemic control values. Each heart thus served as its own control.

pH AND PROTECTION OF THE MATURE HEART. The following experiments were performed in random order in ten groups of 6 mature hearts each to test the null hypothesis that protection of the ischemic mature rabbit heart is unaffected by the pH of the coronary perfusate. The protocol used for this experiment was the same as that described for the immature hearts except that the mature hearts were subjected to 3 hours of ischemia.

(1) MEASUREMENT OF INDICES OF FUNCTION. Aortic flow was defined as the ability of the heart to eject perfusate against the hydrostatic head, with flow rate measured using an in-line analog flowmeter (Biomedix). Coronary flow rate was defined by timed collections of the effluent from the right heart into a graduated cylinder. Electrical activity and heart rate were evaluated from electrocardiographic recordings obtained from leads attached to the aortic and atrial cannulas.

(2) CREATINE KINASE DETERMINATION. The entire coronary effluent during the Langendorff reperfusion period was collected in a graduated cylinder surrounded by ice. Bovine serum albumin was added to the cylinder to achieve a final concentration of 5% (wt/vol) to stabilize the enzyme. After its volume was recorded and the contents of the flask were mixed, an aliquot of the coronary effluent was taken for the determination of total creatine kinase (ATP: creatine *N*-phosphotransferase) [16] activity.

pH AND CALCIUM ACTIVITY OF THE CARDIOPLEGIC SOLUTION. The impact of pH on the calcium activity of the cardioplegic solution at 14°C was measured using a calcium ion-selective electrode mounted inside a beaker containing 1,000 mL of the cardioplegic solution. The solution was maintained at 14°C and continuously stirred. The calcium ion concentration of the cardioplegic solution containing 1.2 millimoles of total calcium per liter was measured under steady-state conditions in eight separate experiments during a gradual change in solution pH from 4.8 to 9.3 over 60 minutes.

Calcium activity at 14°C was determined using a fresh calcium ion-selective electrode (model 93-20; Orion Research Inc, Cambridge, MA) and a liquid-junction reference electrode (Orion model 90-01). Electrode calibration was carried out using calcium standards of identical ionic strength with those of the cardioplegic solution. This allowed the calcium ion concentration to be reported as free calcium ion activity. The change in electrical potential in these solutions developed between the calcium ion and reference electrode were measured using a digital voltmeter. Steady-state changes in potential were obtained within 1 minute. Interference by pH with the measurement of calcium ion activity was determined by changing the pH of the calcium calibration solutions. In six experiments, the mean shift in the calibration curve for 1.0 millimoles of calcium per liter per unit rise in pH was not significant ($p > 0.1$). The total (elemental) calcium content of the cardioplegic solution was determined using an IL-357 atomic absorption spectrophotometer (Instrumentation Laboratories).

IMPACT OF TEMPERATURE ON MEASUREMENT OF pH OF THE CORONARY PERFUSATE. The effect of temperature on the measurement of the pH of both St. Thomas' II solution and Krebs-Henseleit bicarbonate buffer was determined over the range 10° to 40°C. For each temperature studied, the pH electrode was recalibrated against known standards at each temperature. Steady-state levels in pH were obtained within 1 minute of achieving the desired temperature.

Expression of Results

Aortic flow rate was expressed as a percentage of its preischemic control value. Creatine kinase leakage, corrected for the volume of coronary effluent collected during the Langendorff reperfusion period, was expressed as international units released per 15 minutes per gram of dry weight. Calcium ion concentration was expressed as free calcium ion activity in millimoles per liter. Total calcium content was expressed in millimoles per liter.

Fig 1. pH and cardioplegic protection in the immature heart: relationship between postischemic recovery of aortic flow and pH of pre-ischemic perfusate. Closed histograms represent data from hearts protected by hypothermia plus cardioplegia. The open histogram represents data from hearts protected by hypothermia alone. Data shown represent the mean $\pm$ the standard deviation from 6 hearts per group. (+ = $p < 0.05$, hypothermia plus cardioplegia: pH 7.8 versus modified pH; # = $p < 0.05$, hypothermia alone versus hypothermia plus cardioplegia.)

Six hearts were used for each condition studied, and the results were expressed as the mean $\pm$ the standard deviation of the mean. Statistical analysis was performed using the Kruskal-Wallis nonparametric analysis of variance by ranks as a first step, and where this proved significant, the Mann-Whitney test was used as a second step to identify which groups were significantly different [17]. Significance was accepted at the level of p less than 0.05.

Results

Baseline Measurements

Baseline data for the two age groups are shown in Table 1. The hemodynamic stability of the model was assessed by perfusing hearts in the working mode for 160 minutes with nonrecirculating perfusate. No significant changes in heart rate or aortic flow occurred until after 90 minutes of perfusion in immature hearts and 110 minutes in mature hearts. In the studies described that test our hypotheses, the hearts were perfused in the working mode for a maximum of 70 minutes, well within the stability limits of the preparation.

pH and Protection of Immature Heart

FUNCTIONAL RECOVERY. Figure 1 illustrates several findings with respect to the pH of the coronary perfusate and recovery of aortic flow in immature hearts subjected to hypothermic ischemia. First, recovery of aortic flow in immature hearts protected by hypothermia alone ($82\% \pm 4\%$) was better than with the standard (pH 7.8) St. Thomas' II solution ($72\% \pm 2\%$) ($p < 0.05$). Second, a

bell-shaped dose-response profile for pH and functional recovery was observed. As the pH of St. Thomas' II solution progressively decreased from its normal value of 7.8, the percent recovery of aortic flow increased. Optimal recovery of aortic flow with the modified cardioplegic solution occurred at a pH of 6.8. Recovery of aortic flow in this group was $98\% \pm 3\%$. This was significantly greater than with protection provided by either hypothermia alone ($82\% \pm 4\%$) or standard St. Thomas' II solution ($72\% \pm 2\%$) (both, $p < 0.05$). When the pH of the cardioplegic solution was increased from its normal value of 7.8, there was a progressive decline in recovery of aortic flow to $26\% \pm 7\%$ at pH 8.8. The electrical systems of immature hearts tolerated ischemia well regardless of the broad range of pH studied. All hearts returned spontaneously to normal sinus rhythm within 30 seconds after reperfusion. There were no significant changes in heart rate on reperfusion for any of the hydrogen ion concentrations investigated.

POSTISCHEMIC ENZYME LEAKAGE. Figure 2 shows that for immature hearts protected with hypothermia alone (pH 7.25), creatine kinase leakage during the 15-minute Langendorff reperfusion period was 59 ± 19 IU/g dry weight. When hearts were protected by hypothermia plus unmodified St. Thomas' II solution (pH 7.8), creatine kinase leakage was 70 ± 9 IU/g dry weight ($p =$ not significant). In hearts where the pH of the cardioplegic solution was modified over the range 4.8 to 8.8, there were no differences in postischemic creatine kinase leakage compared with that in hearts protected by hypothermia alone and hypothermia plus the unmodified cardioplegic solution.

pH and Protection of the Mature Heart

FUNCTIONAL RECOVERY. Figure 3 shows the relationship between the pH of the coronary perfusate and recovery of

Fig 2. pH and cardioplegic protection in the immature heart: relationship between postischemic creatine kinase leakage and pH of the pre-ischemic perfusate. Closed histograms represent data from hearts protected by hypothermia plus cardioplegia. The open histogram represents data from hearts protected by hypothermia alone. Data shown represent the mean $\pm$ the standard deviation from 6 hearts per group.

aortic flow in mature hearts. No hearts protected with hypothermia alone were able to generate aortic flow or even sufficient ventricular pressure to maintain the hydrostatic column of perfusate. Protection of mature hearts with the standard St. Thomas' II solution resulted in $60\% \pm 8\%$ recovery of aortic flow. The bell-shaped dose-response profile for pH and recovery of aortic flow observed for mature hearts was similar to that observed for immature hearts. As the pH of the cardioplegic solution was reduced from its standard value of 7.8, recovery of aortic flow progressively increased. Optimal recovery of aortic flow with the modified cardioplegic solution occurred at a pH of 6.8. Recovery of aortic flow at this slightly acidic pH was $84\% \pm 5\%$; this was greater ($p < 0.05$) than in hearts protected by the standard cardioplegic solution ($60\% \pm 8\%$). As the pH of St. Thomas' II solution was increased further to more alkaline values, there was a sharp decline in recovery of aortic flow. In contrast to immature hearts, mature hearts were much less able to tolerate extremes of pH. All hearts treated with cardioplegic solution returned spontaneously to normal sinus rhythm within 60 seconds after reperfusion. Heart rate was depressed on reperfusion for hearts exposed to extreme acidic (pH < 5.8) and alkaline (pH > 8.3) environments, but these differences were not significant.

POSTISCHEMIC ENZYME LEAKAGE. Figure 4 shows that for mature hearts protected with hypothermia alone, where the pH of the coronary perfusate was 7.25, creatine kinase leakage during the 15-minute Langendorff reperfusion period was 181 ± 22 IU/g dry weight. When hearts were protected by hypothermia plus the standard St. Thomas'

Fig 3. pH and cardioplegic protection in the mature heart: relationship between postischemic recovery of aortic flow and pH of the pre-ischemic perfusate. Closed histograms represent data from hearts protected by hypothermia plus cardioplegia. The asterisk represents data from hearts protected by hypothermia alone; there was no recovery of function. Data shown represent the mean $\pm$ the standard deviation from 6 hearts per group. (+ = $p < 0.05$, hypothermia plus cardioplegia; pH 7.8 versus modified pH; # = $p < 0.05$, hypothermia alone versus hypothermia plus cardioplegia.)

Fig 4. pH and cardioplegic protection in the mature heart: relationship between postischemic creatine kinase leakage and pH of pre-ischemic perfusate. Closed histograms represent data from hearts protected by hypothermia plus cardioplegia. The open histogram represents data from hearts protected by hypothermia alone. Data shown represent the mean $\pm$ the standard deviation from 6 hearts per group. II solution (pH 7.8), creatine kinase leakage was reduced to 75 ± 15 IU/g dry weight. In contrast to immature hearts, a more pronounced U-shaped dose-response profile was observed for pH and creatine kinase leakage in mature hearts. As the pH of the cardioplegic solution decreased from its normal value of 7.8, there was a decline in postischemic enzyme leakage with a nadir of 55 ± 8 IU/g dry weight at a pH of 6.8. However, as the pH of the cardioplegic solution was reduced to even more acidic values, creatine kinase leakage gradually increased to 124 ± 25 IU/g dry weight at pH 4.8. Similarly, as pH was gradually made more alkaline, creatine kinase leakage progressively increased to 102 ± 16 IU/g dry weight at pH 8.8.

pH and Calcium Activity of Cardioplegic Solution

Figure 5 shows the relationship between pH and calcium activity of the cardioplegic solution. For the unmodified cardioplegic solution (pH 7.8), calcium activity was 1.07 ± 0.01 mmol/L. Titration of the solution to a more acidic or alkaline pH resulted in a bell-shaped dose-response profile for ionized calcium and hydrogen ion concentrations. The calcium ion activity at pH 4.8 and 9.3 was depressed to 0.91 ± 0.02 mmol/L and 0.84 ± 0.02 mmol/L, respectively. There were no significant changes in calcium ion activity over the pH range 6.3 to 8.3. The total (elemental) calcium content of the cardioplegic solution was 1.2 ± 0.01 mmol/L.

pH and Temperature of Coronary Perfusates

Figure 6 shows the relationship between temperature and measurement of pH for the two coronary perfusates. The

Fig 5. pH and calcium activity of the cardioplegic solution. The solid line represents the total (elemental) calcium content of the cardioplegic solution. The solid bars represent the calcium activity of the cardioplegic solution. Data shown represent the mean and the standard deviation from 8 separate determinations at each temperature. (+ = $p < 0.05$, calcium activity at pH 7.8 versus calcium activity at modified pH.)

pH of the St. Thomas' II cardioplegic solution was titrated initially to a value of 7.80 ± 0.01 at 14°C . As the temperature of the solution was progressively increased, the pH declined slightly to 7.76 ± 0.02 at 40°C ($p < 0.05$). When temperature was decreased from 14°C to 10°C , the pH of the solution was no different: 7.80 ± 0.01 versus 7.81 ± 0.01 , respectively. The pH of the Krebs-Henseleit bicarbonate buffer was 7.41 ± 0.02 at a temperature of 40°C . When the temperature was reduced, the pH of this buffer progressively declined to 7.19 ± 0.02 at 10°C ($p < 0.05$).

Comment

Our study demonstrates that improved cardioplegic protection of isolated, bicarbonate buffer-perfused immature and mature hearts subjected to conditions of hypothermic ischemia occurred at a pH of 6.8 as measured at 14°C . This improvement in myocardial protection by mild acidification of the cardioplegic solution was independent of age. The standard pH (7.8) of St. Thomas' II solution is less than optimal for protection of the ischemic immature and mature myocardium. Modification of the pH to 6.8 had no impact on the calcium activity of the cardioplegic solution. Changes in temperature had only a slight effect on the measurement of pH and were unable to account for the observed changes of pH on cardioplegic protection.

Experimental Model

Rabbits were selected for these studies because we [3-5] and others [18] have shown that the ischemic immature heart of this species is damaged by St. Thomas' II cardioplegic solution. The isolated heart model selected allows aspects of left heart function and metabolism to be effectively studied in the same preparation over a wide

range of experimental conditions with the heart subjected to a physiologic work load and temperature. In addition, this model has stable mechanical function with perfusate composition well controlled and easily exchanged within seconds. Through preliminary studies, we carefully defined the in vivo aortic pressure to which hearts were exposed and then matched the hydrostatic pressure of the isolated hearts to the level appropriate to the immature and mature rabbit [13].

The limitations of this type of perfusion system are well known. Aqueous solutions free of red cells, protein, and fatty acid are used to perfuse the coronary arteries. These factors serve to buffer blood-perfused preparations over a wide range of temperatures. In addition noncoronary collateral flow is absent. The hearts are maintained at relatively low end-diastolic values with no assessment made of their response to more stressful working conditions.

pH and Cardioplegic Protection of Immature and Mature Hearts

We have shown that in the isolated buffer-perfused immature heart there is a bell-shaped dose-response profile for the relationship between pH and recovery of aortic flow but not for postischemic creatine kinase leakage, with protection by the cardioplegic solution improved at an acidic pH during ischemia. Optimal myocardial protection with modified St. Thomas' II solution occurred at pH 6.8, which was better than with hypothermia alone (pH 7.25). The absence of a relationship between functional recovery and postischemic creatine kinase leakage for the immature heart calls into question the utility of enzyme leakage as a meaningful index of myocardial protection in the immature heart. We observed a bell-

Fig 6. pH and temperature of coronary perfusates. Open circles represent data from St. Thomas' II cardioplegic solution, and closed circles represent data from Krebs-Henseleit bicarbonate buffer. Data shown represent the mean $\pm$ the standard deviation from six temperature observations in each group. (+ = $p < 0.05$, St. Thomas' II solution: pH at 14°C versus pH at other temperatures; # = $p < 0.05$, Krebs-Henseleit bicarbonate buffer: pH at 40°C versus pH at other temperatures.)

shaped dose-response curve for recovery of aortic flow and a U-shaped dose-response curve for postischemic creatine kinase leakage in the mature heart, with improved protection again occurring at a mildly acidic pH. Optimal myocardial protection of the mature heart also occurred at pH 6.8. These observations indicate that improved cardioplegic protection at a mildly acidic pH occurred regardless of the age of the heart at the time of study. The immature heart tolerated extremes of pH better than the mature heart. This may reflect the greater buffering capacity of the immature heart [19].

pH and Cardioplegic Protection

The assertion that alkaline cardioplegic solutions are best to protect the heart during ischemia was originated by Buckberg and colleagues [20-22]. To allow metabolism to continue under hypothermic conditions, poikilotherms maintain their blood pH at an alkaline value relative to the neutral point of water [8, 9]. Based on this physiological adaptation to keep pH appropriate for temperature in cold-blooded vertebrates, McConnell and co-workers [20] demonstrated that myocardial function and metabolism in warm-blooded dogs improved when blood pH was increased from 7.4 to 7.7 during hypothermic perfusion of the heart. Subsequent studies by Follette and associates [21] showed that a transient increase in the pH of blood from 7.4 to 7.8 during hypothermic reperfusion of the puppy heart after ischemia improved recovery of function. Following these studies that demonstrated the protective effect of alkaline hypothermic perfusion and reperfusion, it was assumed that alkaline conditions would also be appropriate to protect the heart during ischemia. This belief was supported in part by the fact that toxic acidic metabolites are known to be produced during ischemia [7]. Thus the potential existed for attenuating the onset and development of acidic conditions with the provision of an extracellular alkaline environment before and throughout ischemia. Based on these considerations, alkaline cardioplegic solutions were introduced into clinical use [13, 22].

Our study has demonstrated that titration of the pH of St. Thomas' II solution to mildly acidic values improved recovery of both immature and mature hearts after hypothermic ischemia. This paradoxical finding, in contrast to the studies of Buckberg and co-workers [20-22], is supported by considerable experimental evidence. For example, in studies on the hypoxic adult rat papillary muscle, functional recovery was increased in muscle bathed in acidic conditions during hypoxia [23]. Further support for the creation of an acidic environment during ischemia was provided by Rouslin and associates [24]. They determined that an increased hydrogen ion concentration inhibited the net rate of tissue adenosine triphosphate depletion in an autolytic model of cardiac ischemia, resulting in better preservation of high-energy phosphate stores. Poole-Wilson [25] has shown that a mild intracellular acidosis during hypoxia inhibits adverse calcium fluxes and calcium loading of mitochondria after reoxygenation. These events favor improved functional recovery. In addition, Janke and colleagues [26] demonstrated that mature

hearts can be protected against isoproterenol-induced calcium overload by decreasing arterial blood pH to counterbalance the adverse effect of calcium uptake.

To our knowledge, there have been no studies on pH and cardioplegic protection of the ischemic immature myocardium. However, the impact of the pH of the cardioplegic solution on myocardial protection in the adult has been investigated previously. Bernard and associates [27] studied the effect of cardioplegic solutions buffered to pH 7.0, 7.4, and 7.7 on intracellular pH as measured by phosphorus 31 nuclear magnetic resonance spectroscopy and on functional recovery as measured by aortic flow after 2 hours of global ischemia at 15°C in the rat. Hearts protected with the cardioplegic solution buffered to pH 7.0 were characterized by better preservation of adenosine triphosphate levels throughout ischemia and reperfusion and an improved rate of restoration of aortic flow during reperfusion in comparison with the alkaline cardioplegic solutions. In studies of cardioplegic solutions and postischemic function in the dog, Nugent and co-authors [28] demonstrated that alkaline cardioplegic solutions depressed left ventricular function and metabolism more than neutral or acidic cardioplegic solutions.

Mechanisms of Acidic Protection

There are a number of potential mechanisms that may account for the effects we described. Extracellular acidosis may be exerting a protective effect on the ischemic myocardium through a limitation of intracellular calcium accumulation. Intracellular calcium overload can severely limit postischemic recovery of function. It has been proposed that during ischemia the late fall in intracellular pH inhibits sodium-calcium exchange [29, 30]. Assuming a reduction in extracellular pH at the onset of and throughout ischemia would result in a corresponding reduction in intracellular pH, then acidic conditions might be expected to inhibit intracellular sodium-dependent calcium influx. In addition, an increase in the extracellular concentration of protons may also limit sodium influx during ischemia through the sodium-hydrogen exchanger. This inhibition would limit calcium influx by decreasing intracellular sodium accumulation through this exchanger [31]. Ischemic acidosis is known to result from the retention of protons from glycolytic turnover, the accumulation of carbon dioxide, and eventually the breakdown of adenosine triphosphate. These processes are all injurious to the myocardium. The provision of an acidic environment immediately before and throughout ischemia may act to slow these changes, thus preserving cell viability.

pH and Calcium Activity of the Cardioplegic Solution

The existing calcium content of standard St. Thomas' II solution also plays a role in its less than optimal protection of both immature [6] and mature [32] hearts under conditions of clinically relevant hypothermia. We have shown that over the pH range of 6.3 to 8.3, where the pH-modified cardioplegic solution exerted an increased protection compared with the unmodified cardioplegic solution (pH 7.8), the calcium activity of the solution was unchanged. Thus pH had no impact on the calcium

content of the cardioplegic solution that could have altered its ability to protect the ischemic myocardium.

Temperature and pH of the Cardioplegic Solution

The pH of St. Thomas' II cardioplegic solution changed only 0.05 units over the temperature range 10° to 40°C. This indicated that there was no change in the pH of the solution with temperature large enough to have an impact on myocardial protection. The dose-response profile for pH, therefore, was not shifted by temperature. This observation shows clearly that St. Thomas' II cardioplegic solution, which is a bicarbonate-containing solution, is a poor buffer when used under hypothermic conditions. Its poor buffering capacity can be anticipated, as its pH does not parallel the change in the value for the neutrality point of water (pN) during progressive cooling. We emphasize that the choice of a given buffer to be included in a crystalloid cardioplegic solution should be dependent on its temperature coefficient.

The pH of St. Thomas' II solution is mildly alkaline at 7.8. We know of no studies that determine whether myocardial protection with St. Thomas' II solution is optimal at this alkaline pH. The value of 7.8 was selected on the basis of reports [8, 9] suggesting that a mildly alkaline solution was desirable in view of the rise in pH of blood in vitro that occurs on cooling [33]. This effect does not occur with St. Thomas' II cardioplegia, which is an aqueous solution, as cooling produced very little change in pH [20-22]. Thus we are unable to reconcile fully our results for the observed protective effect of an acidic aqueous cardioplegic solution with those of Buckberg, who has advocated the use of alkaline blood cardioplegic solutions on the basis of pH changes with temperature.

Temperature and pH of Bicarbonate Buffer

Temperature exerts a strong influence on the acid-base status of individual coronary perfusates. The acid-base status of the blood in vitro varies with temperature because of changes in the dissociation of weak acids, particularly carbonic acid, and proteins as well as the change in the solubility of carbon dioxide. Siggard-Andersen [12] has shown that a decrease in the temperature of blood at a constant carbon dioxide tension results in an increase in pH. However, for a simple bicarbonate buffer as used in our study, a decrease in temperature at a constant carbon dioxide tension results in a decrease in pH. This relationship can be predicted from the van't Hoff and Henderson-Hasselbach equations [12]. We confirmed this in the present study.

Temperature and Measurement of Perfusate pH

The variation in pH with temperature can lead to difficulties in pH measurement in physiological situations with hypothermia. In our study, the pH of the coronary perfusates was determined at 14°C, a temperature commonly achieved during intraoperative myocardial protection. The variation in pH of an aqueous cardioplegic solution such as St. Thomas' II over the temperature change from 10° to 40°C was small. However, the impact of hypothermia on the measurement of pH of blood

would be much greater [33]. Ream and colleagues [34] have advocated that the measurement of pH at hypothermic temperature be without correction for the known changes in pH with temperature. The correction of pH with respect to temperature in assessing the acid-base status of blood perfusates requires further study.

Conclusion

In conclusion, we have shown that cardioplegic protection of the ischemic rabbit heart is improved under mildly acidic conditions. This effect is independent of the age of the heart at the time of study. It is apparent that the existing pH of St. Thomas' II cardioplegic solution is less than optimal to protect the ischemic immature myocardium in this model. The underlying mechanism responsible for this effect remains to be determined but places into question the dogma that alkaline cardioplegic solutions are best to protect the ischemic heart. Our studies relate only to the protection of isolated buffer-perfused hearts and not to in vivo blood-perfused preparations. Caution must also be applied in extrapolating these results to the clinical situation, as the studies described here relate only to the normal, healthy heart and do not reflect the impact of an underlying disease state on tolerance to ischemia and protection with cardioplegic solutions.

This work was supported by grant HL 43030 from the National Institutes of Health and by Ronald McDonald Children's Charities.

We thank Bob Byrnes, PhD, for assistance in determining the total calcium content of the cardioplegic solution and Matthew Biebel, BS, for determining the calcium ion activity of the cardioplegic solution. The secretarial assistance of Mary Lynne Koenig is gratefully acknowledged by J.E.B.

Delayed Myocardial Laceration After Intrapericardial Pneumonectomy

Blake C. Papsin, MD, Lyall A. Gorenstein, MD, and Melvyn Goldberg, MD

Division of Thoracic Surgery, Mount Sinai Hospital, Toronto, Ontario, Canada

Curative resection for large central bronchogenic tumors may require radical or intrapericardial pneumonectomy. Myocardial herniation through the pericardial defect is a rare early postoperative complication. Prevention of cardiac herniation and subsequent hemodynamic compromise is always necessary after intrapericardial pneumonectomy.

(*Ann Thorac Surg* 1993;55:756-7)

A 72-year-old man was found to have a left hilar squamous cell bronchogenic carcinoma. Resectability was assessed by bronchoscopy, computed tomographic scan of the thorax, and mediastinoscopy.

At thoracotomy the tumor was centrally located and attached to the left pulmonary artery at its origin with the main pulmonary trunk. The pericardium was opened longitudinally anterior to the phrenic nerve from the hilum to within 3 cm of the diaphragm to facilitate ligation of the hilar vessels. The left pulmonary artery was clamped at its junction with the main pulmonary artery, divided, and suture ligated. The pulmonary veins were stapled flush with the left atrium. After completion of the resection, the pericardial defect, which measured approximately 8 cm by 4 cm, was not repaired. The mediastinum was balanced by removing 1 L of air through a red rubber catheter, which was then removed. The patient was extubated in the operating room (Fig 1).

The first postoperative day was complicated by sinus bradycardia. An electrocardiogram revealed low voltage in all leads, flipped T waves in lead III and the precordial leads, and nonspecific ST changes. Serum creatinine kinase level was elevated but the MB fraction was within normal limits.

On the second postoperative day hypovolemic shock developed (Fig 2). After fluid resuscitation a left thoracotomy was performed. The chest was evacuated of blood and clot. All the hilar sutures were secure. The heart had herniated from the pericardium, the apex of the left ventricle was edematous and hypokinetic, and a distal branch of the left anterior descending artery in the center of the injured myocardium was bleeding. The vessel was oversewn and the remainder of the pericardium was

divided to the diaphragm to prevent incarceration of the left ventricle.

The patient left the hospital 10 days after his second operation having followed a smooth postoperative course.

Comment

Cardiac herniation after intrapericardial pneumonectomy is a rarely reported complication associated in the literature with a 50% mortality [1, 2]. Reported cases have occurred with pericardial defects of any size [2, 3], and even when partial or complete closure of the pericardium is performed at the time of the initial operation [4].

Reported cases have attributed the pathophysiologic result of cardiac herniation to occlusion of the great vessels. Hemodynamic compromise occurs after herniation through either right-sided or left-sided pericardial defects, but superior vena caval syndrome more commonly is observed in association with right-sided defects [4]. A recent review of 50 cases [1] classifies cardiac herniation and its hemodynamic effects by anatomic side: right-sided herniations cause predominantly a diminished

Fig 2. Chest roentgenogram on second postoperative day showed complete opacification of the left hemithorax.

cardiac output by obstruction of the venous return and left-sided herniation more often produces myocardial ischemic and dysrhythmias from diminished coronary blood flow caused by compression of the coronary arteries by the edges of the pericardial defect [5].

In this case, the heart likely herniated from the pericardium in the immediate postoperative period, without any serious hemodynamic effect. Compression of the apex of the left ventricle by the pericardial edges produced myocardial edema and localized ischemia, as evidenced by the electrocardiographic changes. The myocardium and an epicardial artery were lacerated by the anterior border of the resected fifth rib, producing a massive hemothorax.

Small defects adjacent to the pulmonary hila can be closed primarily but are usually left open because cardiac herniation complicated by either torsion or strangulation is very infrequent and closure under tension risks causing

tamponade. When the defect in the pericardium is large and cardiac herniation is possible, two options are available. On the left side, the pericardium can be opened down to the diaphragm [6]. This does not prevent herniation, but cardiac strangulation or infarction is unlikely. On the right side, the defect must be closed. This can be accomplished either by suturing the cut edges of the pericardium to the epicardium [7] or by patching the defect with parietal pleura [8] or fascia lata [9]. Dacron has been used [3]; however, septic complications have thus far limited its use.

Our approach, based on our experience, is to repair all large pericardial defects, regardless of side, after intrapericardial pneumonectomy. We now use Vicryl mesh to repair such defects. This material prevents herniation but is absorbable, thereby eliminating foreign material from the postpneumonectomy space. Efforts should be directed toward preventing cardiac herniation. Vigilant observation must be maintained to assist in early detection of this uncommon complication.

Long-Term Follow-up and Resection of a Postoperative False Aortic Aneurysm

Peter E. Linz, MD, Robert B. Wallace, MD, and William P. Baker, MD

Cardiology Division, National Naval Medical Center, Bethesda, Maryland, and Division of Thoracic and Cardiovascular Surgery, Georgetown University, Washington, DC

This report describes the course and operative findings in a 66-year-old man with a densely calcified false aneurysm of his ascending aorta 19 years after replacement of a severely stenosed bicuspid aortic valve with a McGovern-Chromie prosthesis. This report emphasizes the need to consider this possibility, even in patients with a very remote prior operation.

(*Ann Thorac Surg* 1993;55:758-9)

A 47-year-old man underwent replacement of a densely calcified and severely stenotic bicuspid aortic valve with a McGovern-Chromie prosthesis in May of 1969. A 1-cm sternal dehiscence developed 2 weeks later, which was closed with stainless steel and chromic cat gut suture. He became febrile 4 weeks later, at which time six blood cultures all grew *Staphylococcus epidermidis*. His fever promptly subsided after treatment with vancomycin, and his blood cultures remained sterile thereafter.

During the 19 ensuing years he worked full time as a medical records administrator and remained physically active without cardiovascular symptoms. He was maintained on warfarin sodium and subacute bacterial endocarditis prophylaxis when indicated. Anterior mediastinal calcification was noted on a routine follow-up lateral chest roentgenogram, and review of previous films revealed these findings to have been present but less prominent during the preceding 8 years. Computed tomographic scan revealed a large false aneurysm of the ascending aorta arising in the region of the previous aortotomy and extending to the sternum (Fig 1). The extent of the false aneurysm was further defined by aortography (Fig 2). The McGovern-Chromie prosthesis continued to function normally by clinical, echocardiographic, and Doppler assessment.

Operation was performed in October 1988 using cardiopulmonary bypass with cannulation of the femoral artery and vena cava by the femoral vein. The patient's temperature was lowered to 22°C. When the sternum was opened the aneurysm was entered, necessitating a brief period of circulatory arrest until the aorta had been

cross-clamped. The aneurysm measured 4.5 cm, was calcified, and involved the aortic suture line. It was densely adherent to the undersurface of the sternum. The 19-year-old McGovern-Chromie valve appeared normal and was not replaced in view of the additional difficult dissection and prolonged perfusion time that would be required. The ascending aorta was replaced with a 30-cm woven Dacron graft. The patient's postoperative course was uneventful, and he was asymptomatic at his most recent evaluation in October 1991.

Comment

False aneurysms have been reported to complicate aortotomy, aortic cross-clamping, cannulation, needle insertion sites, and aortic suture lines. In a series of 1,000 coronary artery bypass graft procedures, pseudoaneurysm accounted for 3% of the late deaths [1]. In a recent report of 31 cases of pseudoaneurysm, formation infection was implicated in 18 cases [2]. Pseudoaneurysm formation has also been reported as a complication of cardiac transplantation in association with infection.

Computed tomographic scan has proven to be invaluable as a guide to surgical management, although magnetic resonance imaging has also been useful [3, 4]. Precise localization of the pseudoaneurysm reported here resulted in the initiation of cardiopulmonary bypass from the groin, which provided an additional margin of safety for the dissection.

The McGovern-Chromie sutureless valve used in the

Fig 2. Aortogram showing the McGovern-Chromie aortic valve with the pseudoaneurysm arising in the ascending aorta adjacent to the sternum.

1960s because of its rapid insertion was subsequently abandoned because of a relatively high incidence of thromboembolic complications and perivalvular leaks.

This case, however, demonstrates that it is possible for the McGovern-Chromie sutureless prosthesis to function normally without complications for a period of more than 22 years.

A previously reported postoperative false aneurysm was recognized during life 9 years after operation [2]. This case indicates that a much longer survival is possible and that this diagnosis should be considered in postoperative patients long after this time period, especially when there has been perioperative infection.

Traumatic Sinus of Valsalva Fistula and Aortic Valve Rupture

Edward G. Murray, MD, Kazutomo Minami, MD, Henry Körtke, MD, Hubert Seggewiß, MD, and Reiner Körfer, MD

Department of Thoracic and Cardiovascular Surgery and Department of Cardiology, Heart Center North Rhine-Westphalia, University of Bochum, Bad Oeynhausen, Germany

A rare case of nonpenetrating trauma-induced fistula from the right sinus of Valsalva to the right atrium and aortic cusp disruption is reported. The trauma occurred 2½ years previously. The fistula was closed with a Dacron patch, and the cusp tear was sutured.

(Ann Thorac Surg 1993;55:760-1)

Traumatic aorto-right atrial fistula after blunt chest trauma is rarely reported. An unusually long delay between the trauma and the development of symptoms can occur; eventually cardiac insufficiency may develop. Therefore it is important to keep in mind the possibility of a complex cardiac lesion: sinus of Valsalva fistula and aortic valve regurgitation.

A 34-year-old railway worker had driven into an oncoming car at a junction 2½ years previously. Chest contusion was diagnosed at the local hospital. Previously he had been robust according to the yearly checkups at the railway occupational medicine department. Three months after the accident he underwent his yearly checkup and a new diastolic murmur was noted. He was referred to a cardiologist, who diagnosed mild aortic insufficiency. Eighteen months later he began to notice a reduction in exercise capacity. Then he noticed marked dyspnea after climbing the steps to the control tower at work. He went back to the cardiologist, who sent him for angiography. At that time his blood pressure was recorded at 125/30 mm Hg. He did not have any overt signs of cardiac failure. An early systolic murmur was heard over the second intercostal space at the right sternal border, and a diastolic murmur was heard over the left sternal border. Electrocardiogram showed bilateral ventricular enlargement and complete right bundle-branch block. Echocardiography done at this time showed enlargement of the left ventricle with an end-diastolic diameter of 71 mm. The right heart chambers were considered normal in size. Color Doppler echocardiography showed mild aortic valve regurgitation. Cardiac catheterization disclosed raised pressure in the right heart: mean atrial pressure was 8 mm Hg; right ventricular pressure was 30/7 mm Hg.

Left ventricular end-diastolic pressure was increased to 20 mm Hg. The oxygen saturation in the right atrium and ventricle was 80%. Aortic angiography revealed a communication between the right coronary sinus and the right atrium (Fig 1). A sinus of Valsalva-right atrial fistula with left to right shunt of 45% of the pulmonary flow was diagnosed.

He was then referred to our hospital for operation. The patient was tall and thin and not in distress (New York Heart Association class II). A continuous murmur (grade 3) was heard along the left sternal border. Color Doppler examination confirmed the diagnosis of sinus of Valsalva fistula, and a jet of aortic insufficiency was also seen.

At operation a rough fistula tract extending from below the right coronary ostium to the septal wall of the right

Fig 1. Aortic angiography revealed a communication between the right coronary sinus and the right atrium.

atrium above the septal cusp of the tricuspid valve was closed with a pericardial patch. On inspection of the aortic valve, several small perforations near the commissure of the right and left coronary cusps were seen. These were closed with Teflon sponge-backed sutures. The patient made an uneventful postoperative recovery and remained in sinus rhythm. Postoperative color Doppler examination confirmed a good result with no valve dysfunction and no shunt.

Comment

This case of delayed development of traumatic sinus of Valsalva fistula supports the hypothesis on the pathogenesis put forward in previous reports [1, 2]. Because of the delay between the trauma and operation it is almost impossible to differentiate from rupture of congenital aneurysm of the sinus of Valsalva. The traumatic tear in the aortic wall dissected into the root, and the wall of the right atrium was subjected to the eroding pressure. In a previous report the delay in this scenario was 18 months [2]. In this report the delay was 2½ years. When the fistula eventually occurs, the rapidity of deterioration in the patient's cardiac status depends on the shunt developed. In our patient a shunt of 45% of the pulmonary circulation was present.

Interesting features of this case are the unusual con-

comitant occurrence of aortic insufficiency, which obscured the diagnosis, and the long delay between the trauma and the fistula rupture. The delay may be explained by the low mean pressure in the aorta. In the only other reported case of a patient with both aortic regurgitation and a sinus of Valsalva-right atrial fistula after nonpenetrating chest injury, the symptoms were attributed to aortic insufficiency [3]. As in our case the signs of aortic valve rupture masked those of the sinus of Valsalva-right atrial fistula, and the presence of the fistula was only detected by preoperative cardiac catheterization.

According to a recent report [4] accurate diagnosis of sinus of Valsalva fistula can be made with color Doppler echocardiograms. Cardiac catheterization and aortography are optional diagnostic procedures.

Successful Repair of Combined Ventricular Septal Rupture and Free Wall Rupture

Hirofumi Ide, MD, Takashi Ino, MD, Akihiro Mizuhara, MD, and
Atsushi Yamaguchi, MD

Department of Cardiovascular Surgery, Omiya Medical Center, Jichi Medical School, Saitama, Japan

The successful surgical repair of combined ventricular septal perforation and free wall rupture (double rupture) after inferior myocardial infarction is reported. Extensive inferior wall infarctectomy was performed, and both defects were closed with a prosthetic patch, using a modification of the technique developed by Daggett. The patient was alive and well 1 year after operation.

(*Ann Thorac Surg* 1993;55:762-3)

We report a case of combined free wall rupture and ventricular septal perforation (double rupture) after inferior myocardial infarction in which surgical repair was successful.

A 63-year-old man was diagnosed as having a ventricular septal perforation, a left ventricular aneurysm, and cardiac failure after an inferior myocardial infarction. He was transferred to our hospital for surgical repair 17 days after the infarction. After admission, a Swan-Ganz catheter was inserted, and the right atrial pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure were 10 mm Hg, 51/16(36) mm Hg, and 20 mm Hg, respectively. The pulmonary to systemic flow ratio was calculated to be 3.3.

Two days after admission, rapid hemodynamic deterioration was observed despite the administration of inotropic drugs and diuretics and institution of intraaortic balloon pump support. Urgent cardiac catheterization was performed, and left ventricular angiography showed a large posterior-inferior aneurysm, with a defect in the inferior ventricular septum, leading to opacification of the right ventricle and pulmonary artery. Coronary angiography showed 99% occlusion of right coronary artery segment 1 and 75% stenosis of left circumflex artery segment 14.

An operation was performed 19 days after the infarction. A median sternotomy was performed, and a substantial hemopericardium was noted. After systemic heparinization, the ascending aorta was cannulated for arterial perfusion, and the superior and inferior venae cavae were cannulated through the right atrial wall to institute cardiopulmonary bypass. A left ventricular vent

was inserted from the right upper pulmonary vein through the left atrium. Rectal temperature was reduced to 26°C. After aortic cross-clamping, crystalloid cardioplegia was instilled into the aortic root, and the heart was cooled topically. Then the heart was dislocated up out of the pericardial sac and examined. Thinning of the ventricular wall in the area of the infarction was observed around the 4PD segment of the coronary artery, and a fibrin clot was adherent to the infarcted area. This region was believed to be the site of the left ventricular free wall rupture. The region was posterior-inferior and measured approximately 4 cm in diameter. The margins of the infarcted myocardium were determined carefully, and the lesion was excised elliptically. The ventricular septal perforation was 1.5 × 2 cm and was located on the apex side of the infarcted free left ventricular wall (Fig 1).

Ticron (American Cyanamid Co, Wayne, NJ) 2-0 interrupted mattress sutures, buttressed with Teflon felt pledgets, were brought through from the right ventricular side of the septal margin circumferentially, a Dacron patch was placed on the left ventricular side of the septal perforation, and sutures were tied. The interrupted mattress sutures in the margin of the septal perforation of the free wall were passed from the patch side to the epicardial surface and buttressed with a Teflon felt strip on the epicardial surface but were not tied at this point (Fig 2). The left ventricular free wall was reconstructed with a Teflon felt patch. Mattress sutures of 2-0 Ticron, buttressed with Teflon felt pledgets, were placed circumferentially from the endocardial surface around the margin of the left ventricular free wall, except at the edge adjacent to the septal perforation, where untied felt strip-reinforced sutures for septal perforation patch closure were used. The patch was trimmed, and the sutures were brought through from the endocardial side to slide the patch down to the epicardial surface of the ventricle (Fig 3). Concomitant revascularization was not performed. The patient was weaned from cardiopulmonary bypass with the aid of an intraaortic balloon pump. The patient was discharged and was classified in New York Heart Association functional class I after a 1-year follow-up.

Comment

As complications of myocardial infarction, clinical case reports of double rupture are rare [1-7], and cases of successful surgical repair are even more rare [1, 3, 4, 6, 7]. Moreover, among the cases reviewed, survivors included only patients with anterior wall infarction, probably in

Accepted for publication May 15, 1992.

Fig 1. Schematic illustration of inferoposterior aspect of heart and the view of excised aneurysm. (LV = left ventricle; RCA = right coronary artery; RV = right ventricle; VSP = ventricular septal perforation; 4PD = segment 4PD of the right coronary artery.)

part due to the anatomic difficulties involved in reconstruction. The factors that contributed to the favorable result in this case include the following: (1) The free wall rupture was not a blowout, but a hemorrhagic dissecting type. (2) Cardiac rupture was delayed, occurring 18 days after infarction. The subacute phase of infarction is a favorable time for reconstruction. The likelihood of a second rupture or failure of the reconstruction is reduced, because the margins of the area of infarction can be determined with greater certainty and myocardial fibrosis and reduced tissue friability allow sutures to be placed more securely. (3) Even after ventricular septal perforation, the patient remained hemodynamically stable until the free wall ruptured. Thus a successful outcome, even when septal perforation has occurred, depends upon careful clinical assessment. Clinicians need to be especially alert to newly evolving or persistent chest pain [1-3] and signs of cardiac tamponade before electromechanical dissociation or circulatory collapse develop. Interestingly, the diagnosis of free wall rupture was not made preoperatively in any reported case, including ours.

Surgical procedures, especially the reconstruction technique, can be ascribed to isolated ventricular septal perforation reconstruction theoretically. Therefore, our method was mostly based on those described by Daggett

Fig 2. Schematic illustration of the reconstruction of ventricular septal perforation and free wall defect. (VSP = ventricular septal perforation.)

Fig 3. Patch reconstruction of ventricular septal perforation and ruptured free wall aneurysm. (LV = left ventricle; RV = right ventricle; VSP = ventricular septal perforation.)

[8]. The main technical factors to consider in the repair of double rupture after inferior infarction include the following: (1) Repair of the septal defect is performed through the left ventricular incision. (2) Complete resection of the infarcted inferoposterior left ventricular wall is essential to prevent delayed rupture. (3) Both the septal and free wall defect are closed by prosthetic patch reconstruction from the left ventricular and epicardial side, respectively, to restore anatomic continuity without tension. We have adopted a noneverted method, reinforced by either felt pledgets or strips to prevent cracking and leakage.

In conclusion, patient salvage after combined ventricular septal perforation and left ventricular free wall rupture secondary to inferior myocardial infarction was achieved; such salvage can be achieved if surgical repair by techniques established for inferoposterior ventricular septal perforation [8] is performed before circulatory collapse or vital organ failure occurs.

Ventricular Septal Defect Creation for Relief of Tunnel Subvalvular Aortic Stenosis

Loïc Macé, MD, Patrice Dervanian, MD, Jean Losay, MD, and Jean Yves Neveux, MD

Department of Cardiac Surgery, Marie Lannelongue Hospital and Paris-Sud University, Paris, France

In infants, the management of severe tunnel subvalvular aortic stenosis associated with hypoplastic aortic annulus remains a major surgical challenge. We report a case of such lesion treated by rerouting the systemic blood flow through a created subpulmonary ventricular septal defect

toward the right ventricular outflow tract and the pulmonary valve. This technique provided complete relief of the left ventricular outflow tract obstruction without the implantation of a systemic prosthetic valve.

(Ann Thorac Surg 1993;55:764-6)

Tunnel subvalvular aortic stenosis (TSVAS) is a circumferential zone of stenotic fibrosis involving the left ventricular outflow tract (LVOT). In most severe cases, the aortic annulus is often hypoplastic. Surgical management of such a form remains a technical challenge, including enlargement of the aortic annulus [1] or palliative bypass [2]. These techniques require prosthetic aortic valve implantation and often fail to provide satisfactory results or appear unsuitable for use in infants. To overcome these drawbacks we elected to perform an operation precluding the use of a left-sided prosthetic valve.

A hypotrophic girl, aged 11 months and weighing 5,780 g, was admitted with a diagnosis of TSVAS associated with aortic annulus hypoplasia. Auscultation revealed a grade 4/6 systolic murmur, and the chest roentgenogram showed a cardiomegaly associated with pulmonary edema. Color-coded Doppler echocardiographic study revealed a severe TSVAS (subaortic diameter, 4 mm) with a hypoplastic aortic annulus (annulus diameter, 5 mm). Septal thickness was 13 mm. Fractional shortening was 0.34. Left ventricle–ascending aorta gradient was 135 mm Hg. Congenital mitral valve abnormalities were noted, including minimal insufficiency and suspicion of a supra-ventricular ring. Emergency surgical treatment without angiographic evaluation was required due to the life-threatening clinical condition. Because of the patient's age and the association of an evolutive hepatic disease (primary sclerosing cholangitis), we did not implant a prosthetic systemic valve.

The operation was performed under standard cardiopulmonary bypass, and myocardial protection was obtained using cold crystalloid cardioplegia. The ascending aorta and pulmonary trunk up to the bifurcation were dissected and controlled. A vertical incision was made on the anterior surface of the aorta (Fig 1) to confirm the LVOT obstruction at both aortic and subaortic levels and

to provide adequate exposure; this incision was not a part of the future repair. The mitral valve was exposed through a left atriotomy. Its examination showed no evidence of supra-ventricular stenosis, and no further approach was performed. Through a transverse infundibulotomy, a large ventricular septal defect (VSD) was created in the infundibular septum away from the medial papillary muscle to preserve the conductive pathways (Fig 2). The initial septal incision was safely performed with the aid of a Hegar dilator placed in the LVOT. Enlargement of the VSD was obtained by predominantly leftward myectomy under direct vision (VSD diameter, 12 mm). The VSD was then baffled to the pulmonary valve using a double velour Dacron patch lined with preserved heterologous pericardium (Fig 3). The main pulmonary artery was then divided. A second vertical aortotomy was performed in the left lateral aspect of the ascending aorta. The proximal main pulmonary artery was obliquely trimmed and anastomosed end-to-side to the aorta using absorbable running suture. Finally, the right ventricular outflow tract was reconstructed using a 14-mm porcine-valved Dacron conduit (Fig 4).

The patient was easily weaned from cardiopulmonary bypass in sinus rhythm with moderate inotropic support. Intraoperative data showed immediate relief of LVOT obstruction with a residual gradient of 30 mm Hg.

The patient's postoperative hemodynamic condition improved and color-coded Doppler echocardiographic examination showed an excellent patency of the created LVOT with a left ventricle–ascending aorta gradient of 20 mm Hg at the septal level. No neo-aortic regurgitation was noted. Right heart function was preserved despite the loss of the outlet portion of the right ventricle. The patient could be extubated on the 15th postoperative day.

Two days later, assisted ventilation was again required for hemodynamic degradation with pulmonary edema. A new Doppler echocardiographic study showed persistence of excellent LVOT patency. However, severe mitral valve dysfunction (insufficiency and stenosis) was noted. Dramatic improvement of the patient's postoperative cardiac output probably worsened the transmitral valve gradient. Reoperation revealed a parachute-like mitral

Accepted for publication May 21, 1992.

Fig 1. Incisions needed for the repair including anterior and left-sided vertical aortotomies, pulmonary trunk division, and right transverse infundibulotomy.

valve. Complex mitral valve repair was obtained for correction of stenosis but could not be technically achieved against insufficiency. Mitral valve replacement was performed with difficulty (mitral annulus diameter, 14 mm), and the patient could not be weaned from cardiopulmonary bypass. Autopsy showed that the mitral valve dysfunction was unrelated to the LVOT repair.

Comment

One of the most important aspects in the surgical management of TSVAS is to precisely determine the size of the

Fig 2. Creation of the ventricular septal defect (shaded area) in the infundibular septum through the right infundibulotomy.

Fig 3. Completion of the new left ventricular outflow tract by tunnelization of the ventricular septal defect followed by pulmonary artery to ascending aorta anastomosis.

aortic annulus [3]. In the presence of a normal-sized aortic annulus, several effective techniques have been described to obtain complete relief of the LVOT obstruction with preservation of the native aortic valve [3, 4].

Fig 4. Right ventricular outflow tract reconstruction using a 14-mm porcine-valved Dacron conduit.

Conversely, in the presence of a hypoplastic aortic annulus, almost all reported technical solutions require a prosthetic aortic valve, which is associated, especially in children, with valve-related complications. In infants, the procedure described by Konno and associates [1] often fails to allow implantation of an available sized prosthetic valve. Nevertheless, such a procedure has been successfully employed in a neonate using a 15-mm pericardial valve, but a redo aortic valve replacement was necessary 2 years later [5]. A modification of the Konno procedure, using cryopreserved allografts for aortic root replacement and aortoventriculoplasty, has been successfully employed in infants [6]. The long-term fate of such reconstructions still needs to be evaluated, especially regarding allograft calcification and growth potential. Moreover, availability of size-matched allografts is not easy to obtain when the patient requires an urgent treatment. Left ventricle-aortic conduit interposition is effective to obtain ventricular decompression, but it is associated with high early and late mortality and morbidity, especially in infants less than 2 years of age [2]. Moreover, extracardiac conduit repair remains a palliative procedure and potentially requires a reintervention.

The inconsistency of these results led us to create the operation described in this report. Similar procedures have been employed successfully in the presence of a preexisting VSD [7]. In our patient, it was necessary to create a subpulmonary VSD, which may safely be performed as demonstrated in a case of transposition of the great arteries with intact ventricular septum and LVOT obstruction [8]. Rare complications of the septal incision (mainly complete heart block) could be potential drawbacks [3, 4]. Based on the observations in congenitally preexistent VSD [7], one might anticipate an intact LVOT growth potential, particularly at the septal level.

In summary, the technique we described reaches the

two main goals in the surgical management of this malformation: (1) at the subvalvular level, to obtain complete relief of the LVOT obstruction; and (2) at the valvular level, to preclude the use of a left-sided prosthetic valve. Obviously, the technical feasibility in infants and the efficacy of this combination of two-level procedures are the sole conclusions that could be made. The real importance of this procedure is not yet determined. However, it may be a useful technical alternative in selected cases of TSVAS.

Intraoperative Transthoracic Ultrasonographic Localization of Occult Lung Lesions

Hani Shennib, MD, and Patrice Bret, MD

Departments of Surgery and Radiology, Montreal General Hospital and McGill University, Montreal, Quebec, Canada

During video-assisted thoracoscopic operations, identification of small peripheral lung nodules can be challenging. We report the use of intraoperative intrathoracic ultrasonography for localization of lung tumors before resection in 2 patients.

(Ann Thorac Surg 1993;55:767-9)

Over the last year, we have seen an explosion of new instrumentation for endoscopic surgery. Video-assisted thoracoscopic surgery has become an important addition to the variety of techniques by which thoracic surgeons are capable of handling diverse intrathoracic problems [1-3]. Wedge resection of peripheral lung lesions, whether for diagnostic or therapeutic purposes, has become one of the most common indications for video-assisted thoracic surgery. Localization of the lung lesion, however, has been one of the major limitations for application of thoracoscopic techniques in the removal of such lesions. Recently Mack and associates [4] proposed the use of computed tomography-guided needle localization, a technique previously used to facilitate localization of nonpalpable breast lesions, as a method that would allow thoracic surgeons to identify a lung lesion during operation. We report the use of intraoperative intrathoracic video-assisted ultrasonography to localize a lung tumor before its removal.

Case Reports

Patient 1

A 67-year-old man was diagnosed as having a central left upper lobe cancer. Because of severe lung dysfunction due to emphysema, the patient was thought not to be a candidate for pneumonectomy. He received curative radiotherapy to the left lung and mediastinum. This resulted in complete radiological response. On a routine 3-month follow-up 1½ years later, the patient was noted to have a 2-cm peripheral nodule in the apical segment of the right upper lobe. At that time, in addition to severe emphysema, radiation pneumonitis to the left lung had also developed (Fig 1). A transthoracic needle aspiration of the right upper lobe nodule confirmed the lesion to be histologically different, ie, second primary lung cancer. The patient was discussed at a Lung Tumor Board meet-

ing and it was thought that the best therapeutic option available to this patient would be an attempt for video-assisted thoracoscopic wedge resection of the right upper lobe lesion.

On the day of the operation, the patient was taken to the radiology department where a 21-gauge breast localization needle was inserted into the tumor under computed tomographic guidance as previously described [4]. After the procedure, tension pneumothorax developed, which necessitated a tube thoracostomy.

The patient was then taken to the operating room. Under general anesthesia with selective left endobronchial intubation, he was put in the right lateral position and the right lung collapsed. Endobronchial suctioning was used to ascertain complete deflation of the right lung. Three thoracic ports were used: two in the anterior and posterior fourth intercostal space and one in the midaxillary sixth intercostal space. The posterior port was used for the purpose of inserting the ultrasonography probe. We used a transvaginal transducer with a convex probe operating at 5 MHz with a portable ultrasound unit (SSD 500; Aloka Inc) (Fig 2). The wire was found displaced in the pleura. The tumor and its margins were clearly defined by ultrasonography, which allowed appropriate positioning of the linear stapling device before firing. At completion of the resection, the operative specimen was further assessed ex vivo by ultrasonography and compared with preresection images to confirm that the tumor was removed in total.

Patient 2

An 83-year-old woman with a new 1.4-cm peripheral right upper lobe nodule was thought to be too frail to undergo thoracotomy for resection. Preoperative evaluation including computed chest tomography confirmed the lesion to be radiologically T1 N0 M0 (Fig 3). A decision was made to resect the nodule thoracoscopically. The patient underwent needle localization of the peripheral tumor under computed tomographic guidance immediately before operation. Thoracic ports similar to those in patient 1 were used. At the time of the operation, the tip of the wire was found to be displaced in the pleura. Methylene blue dye, which was injected simultaneously with needle localization, facilitated identification of the particular region of the lung to be scanned by ultrasonography. A 10-mm rectal probe with a side transducer operating at 5 MHz and a similar ultrasound unit were used to localize the lesion. Interestingly, the lesion was found to be 2 cm away from the methylene blue stain used simultaneously with the needle localization technique. The lesion was

resected widely using linear staplers under direct ultrasonography guidance. The patient had an uneventful recovery.

Comment

Video-assisted thoracoscopic resection is increasingly used for diagnostic and therapeutic purposes. In primary lung cancer, it is currently indicated for high-risk patients who could not tolerate a lobectomy. Metastasectomy and excisional biopsy of other lesions through such minimally invasive procedures may also be advantageous. Although not documented objectively, video-assisted thoracic surgery is perceived to cause less postoperative pain and have shorter duration of hospitalization.

Fig 2. Ultrasound transducer probing the surface of the right upper lobe. A grasper is used to fix the area of the lung being examined. Fluid is injected into the probe-indented area of the lung to improve surface contact of the transducer.

Fig 3. Thoracic computed tomogram of patient 2. Note the 1.4-cm peripheral nodule in the right upper lobe.

An important limitation to video-assisted thoracic surgery is the difficulty in identifying lung lesions as palpation of the lung is not always possible. The use of metal probes intraoperatively does not compensate for the tactile discrimination lost. Even when needle localization is used, it is frequently difficult to define the depth and margins of the lesion to be resected. The use of an ultrasonography probe may provide numerous advantages: (1) It allows identification of the site of the tumor. As the lung is collapsed, the lung lesion may not settle at the same location that it is perceived to be at based on the computed tomographic scan of an inflated lung. (2) Intraoperative intrathoracic ultrasonography may facilitate not only localization of the lesion but also definition of its margins and hence planning of the strategy of resection, eg, stapling or laser. (3) It allows visualization of the relation of the lesion to important vascular and bronchial structures, which may determine the direction of the linear stapling. (4) As linear staplers are applied, the ultrasound probe may be used to guide the placement of these linear staplers and the progression of cutting to safely encompass the whole lesion. (5) At completion of resection it is possible, by repeating the ultrasonographic assessment of the specimen *ex vivo* and by comparing it with preresection images, to ascertain that the lesion has been removed in total.

Although ultrasonography of the lung is not feasible in its inflated state, once the lung is collapsed, it becomes easily scanned. The residual air in the bronchial tree is visible as branching reverberating artifacts, small and larger vessels are also seen, and solid tumors become distinct from the remainder of lung parenchyma. In these 2 cases, we used a 25-mm transvaginal transducer or a 10-mm rectal transducer with a relatively long shaft, which allows manipulation from outside the thorax. By angulating the probe over the collapsed lung, it is possible to scan the whole surface of the lung. A frequency of 5 MHz was sufficient to scan deep enough into the lung parenchyma with adequate quality of imaging in the near field. Filling the pleural cavity with saline solution or indenting the surface of the pleura by gentle pressure

from the tip of the probe together with injection of saline solution locally will improve surface contact of the transducer and result in better resolution. Use of probes with end rather than side transducers, in our opinion, allows for easier maneuvering and scanning of the lung through the restricting thoracic ports. It is likely that other transducers will be developed and used in the future, hopefully with a smaller diameter and a longer shaft. Intraoperative ultrasonography is likely to become the method of choice for localization of occult lesions either alone or together with the technique of needle localization. The latter has numerous disadvantages such as wire dislodgement, logistical difficulties due to timing of the imaging procedure and scheduling of the operation, and the risk of pneumothorax. Marking of the pleural surface of the lung with methylene blue dye, on the other hand, can be very helpful as it can define and restrict the region to be scanned by operative ultrasonography. Our current preference for localization of occult lung lesions is to take the patient to the radiology suite immediately before the operation. The lesion is localized by methylene blue and a

wire under computed tomographic guidance. Intraoperative ultrasonography is then used at the time of thoracoscopy to confirm the site and relation of the tumor and to guide the application of staplers or laser resection.

In summary, this report describes the applicability of intraoperative intrathoracic ultrasonography to localize lung tumors and resect them by video-assisted thoracic surgery.

Management of Patent Saphenous Vein Grafts During Reoperative Coronary Artery Bypass Grafting

Rajsekhar Devineni, MD, Nishit Shah, MB, ChB, and Jacob Kolff, MD

Division of Cardiothoracic Surgery, Conemaugh Memorial Hospital, Johnstown, Pennsylvania

A patient was referred for coronary artery bypass reoperation. After a left internal mammary artery was grafted to the left anterior descending coronary artery, the diseased but patent old saphenous vein graft was ligated. This resulted in severe myocardial failure, which was

corrected only after restoration of flow through the old vein graft. We suggest the decision to ligate or replace an old vein graft should be individualized to avoid the risk of myocardial ischemia.

(Ann Thorac Surg 1993;55:770-1)

Controversy still persists as to the management of partially stenosed or patent vein grafts in patients undergoing reoperative coronary artery bypass grafting. The risk of myocardial ischemia or infarction due to intraoperative embolization of atherosclerotic debris from within existing vein grafts was clearly demonstrated by Keon and colleagues [1]. This has prompted some authors to recommend early proximal ligation of existing vein grafts and replacement of patent vein grafts 5 years old or older at the time of reoperation [2, 3]. We report a case that illustrates the problems associated with ligating a diseased but patent vein graft to the left anterior descending (LAD) coronary artery and replacing it with an internal mammary artery (IMA) graft.

A 61-year-old man was referred for reoperative coronary artery bypass grafting. In 1980 he had undergone coronary bypass with saphenous vein grafts to the LAD coronary artery, right coronary artery, and marginal branch of the circumflex artery. In September 1991 he was hospitalized with unstable angina. Coronary angiography revealed a patent saphenous vein graft to the LAD coronary artery with diffuse luminal irregularities causing up to 40% narrowing. The vein grafts to the circumflex and right coronary arteries were completely occluded, as were all his native arteries. Overall left ventricular function was well preserved.

At reoperation the left IMA (LIMA) was dissected as a pedicle while the remaining long saphenous vein was harvested. The LIMA measured more than 2 mm in diameter with a brisk flow. Intrapericardial adhesions were carefully divided, taking care not to disturb the patent vein graft. After establishment of cardiopulmonary bypass, standard intermittent cold-blood cardioplegic arrest was used to perform three distal anastomoses using

the LIMA to the LAD coronary artery, distal to the old vein graft, and two segments of reversed saphenous vein to the distal right and obtuse marginal coronary arteries. Adequate flow down the LIMA was assured by observing, upon release of the bulldog clamp on the LIMA, the immediate filling of the distal LAD coronary artery and its branches, the rapid return of left ventricular mechanical activity, and the sharp rise in left ventricular apical temperature measured routinely by a myocardial probe. The flows through the vein grafts were measured by the perfusionist during infusion of cardioplegic solution down them (120 mL and 90 mL, respectively, at 100 mm Hg pressure). After the aortic cross-clamp was removed, the heart spontaneously went into a slow sinus rhythm. At this time the old graft to the LAD coronary artery was ligated, after which the heart promptly fibrillated and had to be defibrillated twice. A partial occlusion clamp was applied to the ascending aorta, and the proximal anastomoses of the right coronary and obtuse marginal vein grafts were performed.

Heart contractility and the electrocardiogram appeared normal on cardiopulmonary bypass. Several attempts were made to wean the patient off cardiopulmonary bypass. However, there was evidence of severe left ventricular failure with ischemic anterior wall electrocardiographic changes. An intraaortic balloon pump was inserted through the left common femoral artery. Despite intraaortic balloon pump support hemodynamic instability persisted. At this time it was surmised that the anterior wall of the left ventricle was not receiving sufficient blood from the LIMA graft.

The ligature on the old vein graft was removed and the graft opened proximally to ensure adequate retrograde flow from the LIMA and to wash out atheromatous debris once flow was restored through this graft. The patient was promptly weaned off cardiopulmonary bypass without difficulty and remained hemodynamically stable without pharmacologic or intraaortic balloon pump support. The patient made an uneventful postoperative recovery.

Comment

Grondin and associates [3] have shown that early vein graft manipulation during reoperative coronary artery bypass grafting can result in embolization of atheroma from within vein grafts by mechanical disruption. They recommend early proximal ligation of vein grafts after minimal dissection to initiate cardiopulmonary bypass. In a recent study by Campos and colleagues [4] there was no difference in progression of atherosclerosis between vein grafts that were normal at 5 years and those that had minimal disease. These results suggest that the risk of occlusion or stenosis in vein grafts that have minimal stenoses at 5 years postoperatively is comparable with that in new vein grafts. We agree with minimizing manipulation of vein grafts during reoperation, but believe the decision to ligate or replace an old vein graft should be individualized.

Superior long-term patency rates of IMA grafts have been clearly demonstrated [5]. Concerns have persisted, however, about their possible flow limitations. According to the Poiseuille equation, IMA flow is limited by its internal radius and to a much lesser extent by its length. Flemma and colleagues [6] showed that resting flows through vein grafts were 2.7 times those through IMA grafts. In addition, they presented evidence that the saphenous vein has a greater capacity to increase its flow during periods of increased demand. Intraoperative papaverine is commonly used to increase the size of the IMA and facilitate its use [7]; however, if a large segment of the anterior wall is to be acutely dependent on IMA flow, there will still be instances of perioperative myocardial failure, as occurred in our case, and perhaps longer term myocardial ischemia [8]. To avoid the potential for inadequate flow to a large subserved myocardial mass during

early reperfusion, we recommend leaving a patent saphenous vein graft unligated, thus maintaining dual supply to the coronary vasculature. The IMA graft should remain patent even when competing with a high-flow vein graft as it has been shown to maintain its patency under no-flow situations [9].

Thoracoscopic Transdiaphragmatic Approach for Adrenal Biopsy

Michael J. Mack, MD, Ronald J. Aronoff, MD, Tea E. Acuff, MD, and William H. Ryan, MD

Section of Thoracic Surgery, Humana Hospital Medical City Dallas, Dallas, Texas

The role of thoracoscopy for the management of intrathoracic diseases has expanded with advancement in endoscopic instrumentation and technology. We report a case of thoracoscopic transdiaphragmatic biopsy of an adrenal gland for metastatic carcinoma. The procedure was uncomplicated and the patient was discharged on the sec-

ond postoperative day. The morbidity of traditional approaches for adrenal operation was avoided. Thoracoscopy may be a useful approach in selected patients for adrenal operation.

(*Ann Thorac Surg* 1993;55:772-3)

Numerous surgical approaches to the adrenal gland have been described including anterior, posterior, flank, and thoracoabdominal techniques [1]. Advances in endoscopic surgical instrumentation have expanded the role of thoracoscopy in the management of many intrathoracic conditions. This report describes the successful thoracoscopic transdiaphragmatic biopsy of an adrenal gland.

A 58-year-old man presented with a new left adrenal mass. The patient had a history of a right colectomy for adenocarcinoma 6 years previously. He had a recurrence in his liver, which was successfully treated with intrahepatic 5-fluorouracil. Six months before presentation, he had resection of three metastases in his right lung by thoracoscopic laser techniques. By computed tomography performed in follow-up after this procedure, a new 3.0-cm mass in his left adrenal gland was discovered (Fig 1). A percutaneous needle biopsy of the mass yielded normal adrenal tissue.

To gain tissue confirmation of metastatic disease an open biopsy was thought to be indicated. After induction of anesthesia, a double-lumen endotracheal tube was used to collapse the left lung. A 10-mm telescope and camera (OTV-52; Olympus Corp, Lake Success, NY) was introduced into the chest through a trocar (Surgiport; United States Surgical Corp, Norwalk, CT) placed posterior to the midaxillary line in the ninth intercostal space. No intrathoracic abnormalities were observed. Two additional trocars were placed anteriorly and posteriorly in the ninth and tenth intercostal spaces as access for endoscopic scissors and grasping instruments. A 6-cm radial incision was made posteriorly in the diaphragm to access the retroperitoneum. Using careful sharp and blunt dissection, exploration of the retroperitoneal fat was undertaken until Gerota's fascia was identified. The fascia was opened

superiorly, and an enlarged adrenal gland was identified. An endoscopic fan retractor was used to facilitate exposure. The blood supply to the adrenal gland was managed with endoscopic surgical clips. A biopsy forceps was used to obtain tissue for microscopic analysis, which confirmed metastatic adenocarcinoma in the adrenal gland. The procedure was terminated at that point, but if indicated, complete resection of the adrenal gland could have been easily accomplished. The diaphragm was then reapproximated using the endoscopic hernia stapler (Endo Hernia Stapler; United States Surgical Corp). A chest tube was not used, and the trocar sites were closed with an absorbable subcuticular suture. Total operating time was 135 minutes.

The patient's postoperative course was unremarkable. He was discharged on the morning of the second postoperative day. No parenteral pain medication was required to manage the mild incisional discomfort. The patient resumed full activity on the fourth postoperative day and is presently undergoing chemotherapy. A chest roentgenogram remains normal 4 months postoperatively with no evidence of diaphragmatic herniation.

Comment

Thoracoscopy has had a limited application, until recently, for management of intrathoracic diseases. Improvement in optics, video technology, endoscopic lighting sources, and endoscopic instrumentation have expanded the role of thoracoscopy to include procedures involving the lung, pericardium and mediastinum, and pleura [2].

There are multiple indications for surgical intervention on the adrenal gland. The approach is partially dictated by the adrenal pathology. The anterior transabdominal approach is indicated for lesions that are either large or potentially malignant. It is also indicated for pheochromocytoma to allow for early vascular control and to allow for exploration for bilateral or extraadrenal tumors [3].

The posterior surgical approach was described by

Accepted for publication June 1, 1992.

Address reprint requests to Dr Mack, 7777 Forest Ln, Suite C-202, Dallas, TX 75230.

Fig 1. Computed tomogram demonstrating a left adrenal mass (arrow).

Young [4] more than 50 years ago and is anatomically the most direct route to the adrenal gland. Although the morbidity of this approach is less than with the anterior route, the operative field is relatively small and exposure is restricted. A flank incision has been advocated as being helpful for adrenalectomy in obese patients [3]. The thoracoabdominal approach is usually reserved for large right-sided adrenal masses.

The morbidity associated with adrenalectomy can be as high as 40%, and the mortality is approximately 2% to 4% depending on the indication and approach [5, 6]. The morbidity and pain associated with traditional surgical incisions serve as an impetus to minimally invasive surgical techniques. Thoracoscopy offers the advantage of lessened morbidity from the surgical incision, yet excellent exposure of the retroperitoneum due to optics, magnification, and lighting.

The thoracoscopic approach would not be indicated in patients with pheochromocytoma or large adrenal masses for resection. There are, however, a select group of patients in whom this may become the preferred technique. In our case, we performed a limited biopsy on the

adrenal gland only after a percutaneous needle biopsy was nondiagnostic.

Enlarged adrenal glands are encountered in otherwise operable patients (4.1%) with non-small cell lung cancer [7]. Frequently, there is discovered pathology other than metastatic carcinoma including adenomas, hyperplastic nodules, and cysts. Preoperative percutaneous needle biopsy should first be performed. If nondiagnostic, thoracoscopy at the time of anticipated lung resection could then be used to obtain a definite tissue diagnosis if both lesions were on the same side.

Reyes and associates [8] have reported prolonged survival of 5 patients with lung cancer and adrenal metastases in whom the primary tumor was resected and adrenalectomy performed. Both resections could be managed by thoracoscopy.

In summary, thoracoscopy offers a new approach for operation on the adrenal gland. More experience is necessary before the scope of procedures possible can be determined. In selected patients, the thoracoscopic transdiaphragmatic approach offers lessened morbidity and superior visualization compared with open approaches. As minimally invasive surgical techniques improve, continued modification of standard surgical approaches is likely to happen.

Infected Hepatic *Echinococcus* Cyst Presenting as Recurrent *Escherichia coli* Empyema

Robert Chang, MD, Martha Higgins, MD, Ralph DiLisio, MD, Abdelkader Hawasli, MD, Luis G. Camaro, MD, and Riad Khatib, MD

St. John Hospital and Medical Center, Detroit, Michigan

An 81-year-old man, previously a shepherd in Italy, presented with recurrent *Escherichia coli* empyema over an 8-month period. His empyema was caused by an infected, nonviable hepatic *Echinococcus* cyst that eroded the diaphragm and led to intermittent spillage and pleural seeding. This case demonstrates that when dealing

with *Escherichia coli* empyema, a subdiaphragmatic source ought to be suspected, and among immigrants from areas with prevalent hydatid disease, infected hepatic *Echinococcus* cyst might rarely be the cause.

(*Ann Thorac Surg* 1993;55:774-5)

Escherichia coli is a rare cause of empyema usually associated with *Escherichia coli* pneumonia and less frequently, with spontaneous bacterial peritonitis [1, 2]. Additionally, an intraabdominal focus, such as subphrenic abscess, may erode through the diaphragm and lead to the development of empyema [3]. In all of these circumstances, recurrence of empyema is extremely rare. Recurrence is usually due to inadequate therapy or may represent new seeding of the pleural space because of unrecognized fistula. We present a case of recurrent *Escherichia coli* empyema over an 8-month period due to infected, nonviable hepatic *Echinococcus* cyst.

An 81-year-old man, who was previously a shepherd in Italy, experienced sudden onset of fever, right-sided pleuritic chest pain, and dyspnea. His symptoms included vague abdominal pain, decreased appetite, and a 13.5-kg weight loss over the last 8 months. His medical history was remarkable for hospitalization for right-sided *Escherichia coli* empyema 30 days earlier. He was treated with chest tube drainage and a 14-day course of cefazolin, which was completed 17 days before his admission. He was also hospitalized elsewhere several months earlier with "pneumonia and pleurisy," which was verified later to be *Escherichia coli* empyema without pneumonic process.

His physical examination demonstrated a temperature of 38°C, dullness, absent breath sounds, and decreased vocal fremitus over the right hemithorax plus moderate right upper quadrant abdominal tenderness. His laboratory tests demonstrated the presence of leukocytosis ($11.3 \times 10^9/L$; 78% polymorphonuclear leukocytes), normal serum bilirubin level (6.8 $\mu\text{mol/L}$ [0.4 mg/dL]), and elevated levels of alkaline phosphatase (360 IU/L; normal range, 15 to 130 IU/L), alanine aminotransferase (58 IU/L; normal range, 0 to 45 IU/L), and aspartate aminotrans-

ferase (48 IU/L; normal range, 0 to 40 IU/L). His chest roentgenogram demonstrated the presence of right pleural effusion. Repeat thoracentesis showed grossly purulent fluid that grew *Escherichia coli*. At this point, a subphrenic source of his recurrent empyema was suspected.

Computed tomography of the abdomen was performed. It showed a large calcified cyst (Fig 1). Upon questioning, the patient stated that he was aware of this cyst for many years. It was thought to be an inactive *Echinococcus* cyst based on its characteristic calcification and its stable size over many years of follow-up. For this reason, needle aspiration or closed drainage procedures were not attempted because of fear of anaphylaxis and to avoid spreading potentially quiescent parasite. He underwent exploratory laparotomy, and the cyst was resected. It was found to be communicating through the diaphragm with the right hemithorax and to contain purulent material, which subsequently grew *Escherichia coli*. Microscopic examination of the cyst failed to show any scolex or viable germinal layer. He was treated with intravenous ceftriaxone (1 g/day) and gentamicin (2.5 mg/kg every 18 hours) for 14 days followed by 14 more days of oral ciprofloxacin (500 mg twice per day). He improved remarkably after operation and became asymptomatic with no further recurrences of his empyema.

Comment

Empyema is a recognized complication of pneumonia, bronchopleural fistula, esophageal perforation, or, rarely, a subphrenic source eroding the diaphragm [3, 4]. Although its cause is usually apparent at the time of diagnosis, occasionally the presenting manifestations may not be specific enough for precise determination. In these circumstances, the bacterial cause may help in identifying its source. For example, isolating common respiratory pathogens such as *Streptococcus pneumoniae* or *Haemophilus influenzae* usually indicates a community-acquired pneumonia as the primary pathologic condition. In another

Fig 1. Computed tomogram of the abdomen showing a large, calcified hepatic *Echinococcus* cyst.

instance, the presence of mouth anaerobes may lead to the diagnosis of aspiration pneumonia, ruptured lung abscess, or esophageal perforation. Likewise, isolation of enteric pathogens such as *Escherichia coli*, especially in the absence of pneumonia, should point to an abdominal source with hematogenous spread to the pleura or direct extension through the diaphragm. In our patient, the cause was found to be an infected "burned out" hepatic *Echinococcus* cyst.

We believe that this patient acquired echinococcosis as a shepherd in Italy. His cyst then became nonviable and

calcified. Subsequently, it got secondarily infected, probably from a biliary source. Then infection spread to the dome of the liver and the diaphragm, creating a fistula into the right hemithorax leading to intermittent leakage to the pleural space and recurrent empyema.

Because *Echinococcus* is most prevalent in the Middle East, Australia, New Zealand, eastern and central Europe, and Latin America [5], it should be considered in immigrants of these areas who present with empyema caused by enteric pathogens, particularly in the presence of a cystic defect in the liver. Then proper surgical drainage can be carefully done to avoid scolex spillage and spread of infection [6, 7].

Successful Combined Operation for Mitral Stenosis and Atrial Fibrillation

Masafumi Hioki, MD, Masatoshi Ikeshita, MD, Yoshio Iedokoro, MD, Takashi Nitta, MD, Atsushi Harada, MD, Tetsuo Asano, MD, Shigeo Tanaka, MD, and Tasuku Shoji, MD

Second Department of Surgery, Nippon Medical School, Tokyo, Japan

Simultaneous surgical treatment of mitral stenosis and atrial fibrillation was performed. The patient's postoperative course was uneventful, the rhythm changed to sinus rhythm, and the patient was discharged on the 21st postoperative day in stable condition.

(Ann Thorac Surg 1993;55:776-8)

Most patients with mitral valve disease have suffered from atrial fibrillation (AF) that produces poor hemodynamic conditions and increases the chance of a thromboembolic event. Recently, Cox and his colleagues [1, 2] described the operative technique for the surgical treatment of AF in patients without valvular disease. Atrial fibrillation combined with valvular heart disease often causes difficult postoperative management and decreases the quality of life. These concerns make it very important for those patients suffering from both diseases to undergo simultaneous surgical treatment for the valvular heart disease and AF.

A 54-year-old man was admitted with exertional dyspnea and tachycardic arrhythmia. Echocardiography and cardiac catheterization revealed severe mitral stenosis with mild pulmonary hypertension and thrombus issuing from the appendage in the enlarged left atrium.

The heart was exposed by a median sternotomy. To complete the bypass and to use moderate hypothermia, the aorta was cross-clamped, and modified Young's solu-

This incision was carried caudally to the inferior limbus, and cranially the incision was continued through the roof of the left atrium to the left atrial appendage.

The exposure of the entire mitral annulus was facilitated by placing several retraction sutures; calcified valve and large organized thrombus were recognized and resected carefully. In modifying the maze procedure reported by Cox, we performed a left atrial incision as follows. A vertical posterior left atriotomy was placed 5 mm from the center of the posterior mitral valve annulus to the midway point between the left and right inferior pulmonary veins to expose the fat pad at the atrioventricular groove. In placing this incision, we took care to avoid injuring the circumflex coronary artery, esophagus, and coronary sinus. The incision was extended superiorly to carry between the left and right superior pulmonary veins until it joined the previously placed superior transverse left atriotomy. The posterior left atriotomy was then closed with a continuous 3-0 monofilament suture. After this procedure, we performed mitral valve replacement using a 25-mm Björk-Shiley valve. The transverse atriotomy on the top of the left atrium was then extended into the base of the left atrial appendage, and the appendage was excised. The transverse left atriotomy was closed, beginning at the lateral base of the excised left atrial appendage (Fig 1B). The atrial septotomy was also closed from the bottom of the fossa ovalis toward the top of the atrial septum. The two suture line closures were then secured, which closed the left side of the heart.

Finally we performed the right atrial incisions (Fig 1C). The right atrial incision was made from the superior base of the excised right atrial appendage into the anterior superior vena cava. Then a counterincision was placed in the posterior right atrial free wall, beginning well up into the superior vena cava posteriorly. The posterior right atriotomy was then carried down the lateral free wall of the right atrium and was curved anterior to the inferior vena cava cannula. This incision was carried to the level of the tricuspid valve annulus just posterior to the orifice of the coronary sinus carefully to avoid injury to the right coronary artery. After these incisions were completed, the aortic cross-clamp was released and the left side of the heart was deaired. The right atrial incisions were closed from the posterior wall to the lateral wall with a continuous 4-0 monofilament suture. The aortic cross-clamp time was 123 minutes.

After defibrillation, the heart began beating with junc-

For editorial comment, see page 578.

tion and glucose-insulin-potassium cardioplegic solution were given to arrest and protect the heart. We chose the superior-transseptal approach to the left atrium [3], considering it to be mutually beneficial to the mitral valve procedure and to atrial incisions (Fig 1A).

The right atrium was opened obliquely laterally from the inferior venous cannula to the medial part of the right atrium where it meets the roof of the left atrium. Care was taken not to damage the sinus node. The interatrial septum was opened longitudinally at the fossa ovalis.

Accepted for publication Sep 18, 1992.

Fig 1. (A) Excellent exposure of left atrium and mitral valve apparatus by the combined superior-transseptal approach. (B) After mitral valve replacement, completion of left posterior atriotomy, and transection of left atrial appendage, the suture closures of left atrium and interatrial septum are performed. (C) Right atrial incision, transection of right atrial appendage, and incision of lateral free wall of right atrium just beneath the tricuspid valve annulus are completed. (Ao = aorta; CS = coronary sinus; IVC = inferior vena cava; LA = left atrium; LAA = left atrial appendage; LPV = left pulmonary vein; PA = pulmonary artery; RA = right atrium; RAA = right atrial appendage; RPV = right pulmonary vein; SVC = superior vena cava.)

tional rhythm and the patient was decannulated after the intraaortic balloon pump catheter was inserted. The patient was weaned from the ventilator and intraaortic balloon pump the following day. His postoperative course was uneventful and his heart rhythm showed mainly junctional rhythm for the first week postoperatively (Fig 2). Subsequently, his heart rhythm was converted to sinus rhythm. Cardiac catheterization 3 weeks after the operation confirmed satisfactory postoperative status. He remains well, active, and at work 6 months postoperatively with no evidence of AF.

Comment

Atrial fibrillation develops in 40% to 50% of patients with mitral stenosis [4]. It impairs cardiac performance and

predisposes the patient to systemic emboli. In particular, after valve replacement tachycardic AF resistant to medical treatment decreases cardiac output, and because of the arising severe low output syndrome the postoperative course often becomes eventful. The concept and operative method of surgical treatment of AF was first described in 1991 by Cox and his colleagues. They performed this operation on 14 patients without valvular disease and were rewarded with a successful outcome in all cases. Because we were convinced that this operation would benefit the patient suffering from mitral valvular disease and AF, we performed a simultaneous operation to treat both mitral stenosis and AF. The successful outcome of our case supports our confidence that the simultaneous mitral valve and AF operation will witness widespread clinical application.

Technique of Transplantation for Hypoplastic Left Heart Syndrome With Left Superior Vena Cava

Thomas L. Spray, MD, Charles B. Huddleston, MD, and Charles E. Canter, MD

Divisions of Cardiothoracic Surgery and Pediatric Cardiology, Washington University School of Medicine and St. Louis Children's Hospital, St. Louis, Missouri

The presence of a left superior vena cava in infants with hypoplastic left heart syndrome complicates the technical performance of orthotopic cardiac transplantation. In this report we describe a modification of the recipient cardiectomy to maintain patency of the left superior vena cava, leaving the recipient coronary sinus as a conduit for it into the right atrium and avoiding complex venous reconstructions.

(*Ann Thorac Surg* 1993;55:779-81)

Orthotopic cardiac transplantation for hypoplastic left heart syndrome has become increasingly common after the initial reports by Bailey and associates [1]. The technique of infant cardiac transplantation has been previously described [2]. The presence of an anomalous left superior vena cava (LSVC) entering the coronary sinus of the recipient infant with hypoplastic left heart syndrome, however, presents a problem for orthotopic cardiac transplantation. Previous descriptions of methods of dealing with the LSVC drainage have been oriented toward ligating the LSVC, dividing it and creating an anastomosis to the right superior vena cava, using the donor innominate vein to reconstruct the normal venous drainage, or creating an atrial tunnel [3-5]. Each of these techniques has potential problems. Ligation subjects the patient to risks of unilateral cerebral, facial, and arm edema. Anastomoses of thin-walled veins in neonates are difficult to create without kinking or twisting of the veins. Creating an atrial baffle using pericardium or prosthetic material creates the potential risk of stenosis as the pericardium thickens or an intimal peel forms on the prosthetic material. We have devised an alternative method that leaves the LSVC draining into the coronary sinus *in situ* to avoid the above-mentioned problems and to allow for maximal growth.

Material and Methods

From January 1988 through May 1992, 18 consecutive infants have undergone orthotopic cardiac transplantation for hypoplastic left heart syndrome at St. Louis Children's Hospital, Washington University Medical Center. Three of these infants underwent transplantation after a first-stage Norwood operation for hypoplastic left

heart syndrome. Four of the 18 infants referred for transplantation had an associated large LSVC entering the coronary sinus. The recipient cardiectomy was altered slightly to permit drainage of the LSVC through the coronary sinus orifice into the recipient right atrium to maintain LSVC flow after transplantation.

After hypothermic circulatory arrest, the cannulas for cardiopulmonary bypass are removed from the heart. An incision is made in the anterior wall of the right atrium of the recipient and carried inferiorly below the orifice of the coronary sinus and outside of the heart (Fig 1). The incision is carried superiorly across the roof of the left atrium, leaving as much of a rim of tissue as possible; occasionally the left atrial appendage is left in place to allow sufficient tissue for reconstruction of the left atrium because the LSVC courses posteriorly behind the left atrium entering the coronary sinus in the left atrioventricular groove. When the left atrial appendage is left in place it may be opened longitudinally to its apex to provide more atrial tissue for the anastomosis and also to prevent it from becoming a site for thrombus formation. The atrial septum is divided superior to the coronary sinus orifice. Excision of the heart is completed by incising the left atrioventricular groove above the coronary sinus, dividing the posterior descending and great cardiac veins in the process. Occlusion of the veins can be performed either by individual ligation or by incorporating the veins in the left atrial suture line while implanting the donor heart. The aorta is reconstructed as usual for hypoplastic left heart syndrome. The recipient coronary sinus becomes in effect a conduit for the LSVC with its orifice in the right atrium. In our patients absorbable suture was used for all anastomoses to allow for maximum growth.

Results

All 18 infants are hospital survivors. There has been one late death secondary to chronic pulmonary venous obstructive disease 2 months after transplantation in an infant who had initially been treated with a first-stage Norwood procedure at 1 day of life. Another infant has undergone retransplantation at 1 year of age after acquiring severe transplant coronary artery disease when administration of steroids was discontinued. All 4 infants who had the described repair of the LSVC drainage have done well with no clinical evidence of venous hypertension in the left upper body. Echocardiograms have shown patency of the LSVC with excellent flow into the right atrium in each patient (Fig 2). In 2 infants, a Broviac

Fig 1. (A) Anatomy typical for hypoplastic left heart syndrome with left superior vena cava (LSVC) draining into the right atrium (RA) through the coronary sinus (CS), which is enlarged. (B) The recipient cardiectomy incision in the right atrium is carried outside the heart inferior to the orifice of the coronary sinus near the atrioventricular groove. (C) This is a left anterior oblique view of the heart showing the recipient cardiectomy incision (dotted line) coursing along the roof of the left atrium behind and lateral to the pulmonary artery (PA), then anterior to the LSVc, and finally near the left atrioventricular groove. (D) Anastomosis of the donor and recipient left atria includes the great cardiac and posterior descending coronary veins in the suture line; anastomosis of donor and recipient right atria leaves the recipient CS entering the RA and thus maintains LSVc patency. (Ao = aorta; AoV = aortic valve; IVC = inferior vena cava; PDA = patent ductus arteriosus; PV = pulmonary vein; RSVC = right superior vena cava.)

catheter (Bard Access, Salt Lake City, UT) was placed in the LSVc for blood drawing and intravenous antibiotic therapy (Fig 3), with maintenance of the right superior vena cava for use for endomyocardial biopsy for postoperative monitoring of immunosuppression. The time required for cardiac transplantation was longer for those infants with LSVc; total pump (including circulatory arrest time) and circulatory arrest times for those with LSVc were 113.5 ± 15.6 and 50.5 ± 7.6 minutes, respectively, versus 105.8 ± 4.8 and 41.2 ± 7.2 minutes for those with normal great veins.

Comment

Although many approaches have been described for complex congenital reconstructions with orthotopic cardiac transplantation, a common associated condition in hypoplastic left heart syndrome appears to be the persistence of the LSVc draining into the coronary sinus (22% in our series). As described above, minor alterations in the recipient cardiectomy can facilitate dealing with the LSVc and obviate complex venous reconstructions in infants with hypoplastic left heart syndrome, permitting maximal

opportunity for growth. In rare cases in which the coronary sinus is unroofed into the left atrium, the roof of the coronary sinus can be closed directly before implantation of the donor heart. The technique used in this series can also be used for the adult patient who has an anomalous LSV and requires cardiac transplantation, and is also suitable for use in heart-lung transplantation.

Localized Supravalvar Aortic Stenosis: A New Technique for Repair

Richard B. Chard, FRACS, and Timothy B. Cartmill, FRACS

Department of Cardiac Surgery, Royal Alexandra Hospital for Children, Sydney, New South Wales, Australia

The deformity in supravalvar aortic stenosis includes generalized thickening of the tissues of the aortic root with a fairly normal sized aortic valve ring. The thickened tissues may obstruct the origins of the left and right coronary arteries. We have repaired 2 cases with complete excision of the stenosing ring below the level of the commissures of the aortic valve into the sinuses, to the level of the left and right coronary arteries.

(Ann Thorac Surg 1993;55:782-4)

Localized supravalvar aortic stenosis is a complex anomaly. As Doty [1] has pointed out, not only is supravalvar stenosing ring present, but also a generalized thickening of the tissues in the region of the ring, the proximal ascending aorta, and the sinuses of Valsalva. The aortic valve is deformed by abnormal commissural proximity, leaving the aortic leaflets redundant and often buckled at the free edge. The ring inhibits full opening of the leaflets and causes a jet lesion of the aortic leaflets, leading to progressive regurgitation. The ring may also impinge on the coronary ostia producing stenosis.

Each sinus of Valsalva resembles a diverticulum with a coronary artery emerging from its cupola, below the stenosing ring. The aortic annulus at the level of the base of the leaflets is usually normal sized.

Case Reports

Patient 1

A 6-month-old boy had a murmur noted in infancy. Echocardiography and cardiac catheterization revealed localized supravalvar aortic stenosis, normal pulmonary arteries, severe left ventricular hypertrophy, and a left ventricle to aorta pressure gradient of 120 mm Hg.

Operation was performed using cardiopulmonary bypass and moderate hypothermia. The thymus was excised. The ascending aorta and the aortic arch and its branches were mobilized from the main pulmonary artery and right pulmonary artery and mediastinal tissues (Fig 1). High ascending aortic and right atrial cannulations were used for bypass, and cardioplegia was administered. The aorta was transected at the level of the stenosing ring, and the thickened tissues were excised from the tops of

the commissures down into the sinuses of Valsalva to the ostia of the left main coronary and right coronary arteries. This freed the commissures to move centrifugally, opening up the region. The distal ascending aorta was transected at a level where it was of normal diameter and free of intimal thickening, 1.5 cm distal to the commissures (Fig 2).

The ascending aorta was anastomosed to the aortic root using continuous 7-0 polypropylene, the suture line running from the apex of the commissures down into each sinus of Valsalva, across the cephalad lip of the left main and right main coronary arteries (Fig 3). The aortic clamp time was 21 minutes. Postoperatively, labile hypertension occurred. Repeat cardiac catheterization 13 months postoperatively revealed no supravalvar gradient (Fig 4), trivial aortic regurgitation, and some regression of the left ventricular hypertrophy.

Patient 2

A 2½-year-old boy with William's syndrome and a heart murmur was found to have supravalvar aortic stenosis. Cardiac catheterization revealed a gradient of 100 mm Hg from left ventricle to aorta with no aortic regurgitation, localized supravalvar stenosis, and severe left main coronary ostial obstruction as described above (Fig 5). Echocardiogram after 3 months showed a gradient of 30 mm Hg from left ventricle to aorta and good relief of the coronary artery obstruction.

Comment

This technique is simple and needs no prosthetic material. Most importantly, it symmetrically enlarges the aortic valve mechanism more completely than the technique of Doty, which extends gussets into two of the three sinuses of Valsalva (180 degrees opposite each other) or that of Myers and Waldhausen [2], whose V-Y advancement flaps into the sinuses must be asymmetric to avoid the coronary arteries, possibly distorting the sinuses and valve leaflets. Our method also allows relief of left main coronary obstruction by excision of the stenosing ring flush with the ostium as in patient 2.

Extensive aortic arch mobilization, as in corrective operation for interrupted aortic arch, allows excision of sufficient abnormal tissue to permit primary anastomosis. This should grow like the aortic anastomosis after coarctation resection and end-to-end anastomosis, or arterial switch for transposition. The extent of ascending aorta

Accepted for publication Nov 23, 1992.

Fig 1. Surgeon's view of the mobilized great vessels and supra-valvar aortic stenosis, showing lines of excision (---).

excision might be limited by compression of the left main bronchus or the right pulmonary artery. For longer stenoses a standard patch technique or excision with patch supplementation would allow symmetrical correction of the deformity.

Long-term follow-up of this lesion after surgical correction using patch aortoplasty techniques has demonstrated good symptomatic results. Few hemodynamic data are

Fig 3. After anastomosis of the normal-diameter ascending aorta to the aortic root.

available, although Keane and associates [3] demonstrated residual gradients ranging from 4 to 55 mm Hg with a mean of 27 mm Hg, the more severe predominantly valvar or subvalvar. Flaker and colleagues [4] reported 8 patients among whom, after patch aortoplasty, 4 had aortic transvalvular gradients between 23 and 48 mm Hg and 2 had serious aortic regurgitation but none had serious supra-valvar gradients. These residual gradi-

Fig 2. After excision of the stenosing ring, upper half of sinuses of Valsalva, and stenosed segment.

Fig 4. Aortogram after repair in patient 1.

Fig 5. Aortogram of patient 2 showing tight left main coronary obstruction.

ents and regurgitation probably represent incomplete correction of the deformity.

Myers and Waldhausen [2], in 13 patients, had echocardiographic gradients of 25 to 40 mm Hg in their bifurcated patch repair group and less than 25 mm Hg in the V-Y flap repair group. It should be noted that echocardiography tends to overestimate the severity of gradients in this context [2].

The patch technique can also lead to adhesion of the noncoronary leaflet to the patch, leading to acquired bicuspid aortic valve and severe aortic regurgitation (Van Praagh R; personal communication, April 1992).

This new, safe, simple, and effective technique is recommended as providing the best possible relief of all components of this uncommon lesion.

Transseptal Insertion of Left Atrial Line: A Simple and Safe Technique

Podila Sitarama Rao, MS, MCh, and Ponangi Venkata Sathyanarayana, MS, MCh

Nizam's Institute of Medical Sciences, Punjagutta, Hyderabad, India

The widespread use of left atrial lines underscores the importance of left atrial pressure monitoring in open heart operations. We present a simple and safe method of intraoperative insertion of a left atrial line during an open heart operation. Foremost among the several advantages of this method is that there would no longer be any concern of postoperative bleeding after removal of the left atrial line.

(*Ann Thorac Surg* 1993;55:785-6)

Monitoring of left atrial pressure has an important application after reparative procedures on the mitral valve, after surgical correction of complex congenital cardiac malformations, in operations for ischemic heart disease with left ventricular dysfunction, and during difficulty in weaning from cardiopulmonary bypass. It is an invaluable aid in the management of critically ill patients in the perioperative period after a cardiac operation until the hemodynamic status of the patient has stabilized. Several routes of insertion of the left atrial line have been described. These include insertion through the left atrial suture line, through the right superior pulmonary vein, and through the left atrial appendage. In all these situations, despite several precautions, the surgeon is always concerned about the possibility of bleeding from the puncture site in the postoperative period after removal of the left atrial line. It is not uncommon to delay the removal of chest drains until the left atrial line has been removed to facilitate the early detection of such bleeding. We present here a simple, convenient, and safe method of left atrial line insertion with virtually no possibility of bleeding after left atrial line removal.

Procedure

Two central lines are inserted from the neck through the internal jugular vein or from the arm through the median basilic vein. In operative procedures involving opening of the right atrium, the tip of the previously identified (by injecting few mL of saline solution through one of these lines) central line can be easily slipped into the left atrium through the suture line of the patch closure of an atrial

septal defect or direct closure of a persistent foramen ovale (Figs 1, 2).

In operative procedures not involving opening of the right atrium with an intact interatrial septum; a small atriotomy 1 cm in length is made on the right atrium parallel and just anterior to the interatrial groove (Fig 3A). The atriotomy margins are retracted and the bulging fossa ovalis septum visualized. A small stab incision is made in the fossa ovalis septum using the tip of a no. 11 surgical blade, and the previously identified central line is slipped into the left atrium through this incision (Fig 3B). Due care must be taken to make a very small incision on the interatrial septum. The atriotomy is closed by a continuous suture. In the postoperative period, necessary precautions to guard against systemic air embolism, as applicable to any other left atrial line, should be observed. When left atrial pressure monitoring is no longer needed, the left atrial line can be withdrawn by few centimeters such that it slips back across the septum into the right atrium and assumes the position of a regular central line. This can be confirmed by the dark color of the blood and by blood gas analysis of the aspirated blood.

Comment

This method of intraoperative placement of a transseptal left atrial line is essentially a repositioning of the previously placed central line across the septum, into the left atrium, under direct vision. There are several advantages to this method. First, there is no possibility of external bleeding in the postoperative period after removal of the left atrial line. Second, the left atrial line will be coming out through the neck or arm as any other central line depending on the initial site of insertion. Consequently, the inconvenience in the management of a central line coming straight out of the chest wall can be avoided. Third, unlike a pulmonary artery catheter it can be easily placed even in infants. We also believe that with this method, we would not face the rare but unfortunate predicament of a "stuck" left atrial line that cannot be removed easily by the usual methods.

The small opening made in the interatrial septum can be justifiably expected to close within a short period, as demonstrated in studies [1, 2] that have reported follow-up of punctures in the interatrial septum. Similarly, a transient and very minimal shunt across the interatrial septum, although theoretically possible, was never a source of worry to us. The separate atriotomy in the right atrium would not pose any additional hazard of bleeding as this was closed under direct vision. Thus, we believe

Subclavian Artery Cannulation for Infant Extracorporeal Membrane Oxygenation

Edwin C. McGough, MD, Sharon McGough, RN, and John A. Hawkins, MD

Division of Cardiothoracic Surgery, Primary Children's Medical Center, and University of Utah Medical Center, Salt Lake City, Utah

A technique is presented for subclavian artery cannulation for extracorporeal membrane oxygenation. This method allows antegrade perfusion of the carotid artery to occur both during extracorporeal membrane oxygenation and after decannulation. This method may prevent neurologic sequelae associated with the more common techniques using the carotid artery.

(*Ann Thorac Surg* 1993;55:787-8)

Extracorporeal membrane oxygenation (ECMO) using venoarterial cannulation is an established form of treatment for a variety of forms of respiratory failure in neonates. The most common technique of vessel cannulation involves using the common carotid artery for arterial inflow and the internal jugular vein for venous return. Neurologic complications have been reported after ECMO, and complications attributable to ligation of the carotid or jugular system [1] are difficult to separate from those neurologic complications that result from intraventricular hemorrhage, cerebral edema, preexisting hypoxia, or other factors related to the ECMO perfusion [2]. These factors have led some authors to now recommend carotid artery and in turn jugular vein reconstruction after ECMO [3]. We have developed a technique (Fig 1) that not only preserves the internal carotid artery after decannulation, but also allows antegrade perfusion through the carotid artery during ECMO.

Technique and Patients

The patient is positioned supine in the newborn intensive care unit and is placed on a shoulder roll, and the head is rotated to the left. A short longitudinal incision is made at the lower anterior border of the sternocleidomastoid border in the right neck. The internal jugular vein is first isolated and mobilized. The subclavian artery is identified and isolated by carefully dissecting the carotid artery and retracting it cephalad. The vertebral artery is identified as the first major branch of the subclavian artery on the right side, and it is ligated. The patient is then heparinized and the ECMO perfusion circuit is prepared for cannulation. Through a longitudinal arteriotomy, the arterial cannula is introduced into the subclavian artery and is advanced through the innominate artery so that the tip of the

cannula will lie just inside the lumen of the aortic arch. An Elecath aortic ECMO cannula (Electro-Catheter Corporation, Rahway, NJ) is used, and sizing of the cannula is based on weight of the infant and anticipated flow rates. In general, an 8F aortic inflow cannula is used for infants weighing between 2 and 3 kg and a 10F for those more than 3 kg. A standard internal jugular venous cannulation is then accomplished through a longitudinal venotomy. An Elecath cannula that is specially designed for venous drainage with multiple side holes is used. The largest venous cannula that can be safely inserted is used, usually a 12F in the average neonate. The catheter is positioned so that the tip lies within the right atrium and the last side hole is positioned opposite the innominate vein to prevent venous hypertension in the contralateral internal jugular vein. The wound is then closed in layers in a standard fashion and the cannulas exit from the upper edge of the incision.

When the child is successfully weaned from ECMO the wound is reopened and the cannulas are removed. Both the vein and the artery are allowed to back-bleed to ensure that no thrombus is present. Preferably, the vein and artery are then both primarily repaired with fine polydioxanone sutures. In general these vessels are closed in a transverse fashion to prevent a localized vessel stenosis. If reconstruction is not possible the vessels can be simply ligated.

From January 1989 until December 1991, internal jugular to subclavian artery venoarterial cannulation for ECMO has been used exclusively at our institution. A total of 23 patients underwent ECMO using this cannulation technique during this period. Sixteen patients underwent ligation of the subclavian artery at the time of decannulation, and 7 recent patients underwent reconstruction of the subclavian artery at the time of decannulation. All patients were neonates except for 1 patient who underwent ECMO at 29 months of age. The duration of ECMO ranged from 49 to 220 hours (mean, 141 hours).

Transcranial Doppler evaluation of carotid artery flow was done routinely in all patients immediately after the initiation of ECMO, 24 hours after the beginning of ECMO, and 72 hours after decannulation. These transcranial color Doppler studies showed antegrade flow in the carotid artery and A1 segment of the anterior cerebral artery in all patients during ECMO and at 72 hours after discontinuation of ECMO. Antegrade blood flow during ECMO was also seen in the basilar artery of all patients. Retrograde flow was visualized in the right vertebral

Fig 1. (A) Standard extracorporeal membrane oxygenation cannulation using carotid artery. Ipsilateral internal carotid flow is retrograde through the A1 segment of the anterior cerebral artery. (B) Subclavian extracorporeal membrane oxygenation cannulation preserves antegrade flow in the internal carotid, basilar, and the A1 segment of the anterior cerebral artery. (C) Cannula size that is approximately 75% of the innominate artery size will allow antegrade carotid flow.

artery in 1 patient due to failure to temporarily ligate the right vertebral artery on the ipsilateral side.

Comment

Neurodevelopmental problems in infants after ECMO have been reported in 20% to 35% of patients [1, 2]. The exact cause of these neurologic problems is difficult to isolate, but can be due to intracranial hemorrhage while on ECMO, hypoxic-ischemic encephalopathy, problems related to a carotid ligation, or thromboembolic events during ECMO [1, 2]. Although the exact cause for cerebral dysfunction after ECMO cannot be exactly delineated, the maintenance of antegrade carotid blood flow both during and after ECMO is certainly desirable. The technique we have described preserves antegrade carotid blood flow during ECMO and allows maintenance of antegrade carotid flow after decannulation, even if arterial reconstruction is not technically feasible. Usually the carotid and subclavian vessels in the newborn are quite elastic and it is quite easy to retract these vessels upward and perform this cannulation without difficulty. In our experience, extension of the incision or excessive retraction is not needed to expose the subclavian-innominate arterial junction and perform the cannulation. Although the long-term sequelae of subclavian artery ligation after this technique are not known, long-term problems with subclavian occlusion after subclavian flap arterioplasty or Blalock-Taussig shunts are known and are not severe [4].

It is important in this technique that an arterial cannula that is approximately 75% of the size of the innominate artery is selected so as to allow antegrade carotid flow during ECMO. This can be done by sizing the innominate artery by ultrasound before the institution of ECMO flow. Antegrade flow in the ipsilateral carotid artery was well

demonstrated in this series using the color flow Doppler technique. Other authors have demonstrated abnormal flow velocities in the anterior cerebral vessels after institution of ECMO when the common carotid artery is cannulated [5]. We did not find any flow abnormalities in the anterior cerebral or basilar arteries using this subclavian artery approach. It is important to ligate the vertebral artery on the same side of cannulation, because failure to do so may result in retrograde vertebral flow and the possibility of subclavian steal syndrome.

Although long-term neurologic prognosis may not be different in patients who have carotid cannulation with or without ligation as compared with subclavian artery cannulation, we believe that subclavian artery cannulation offers a unique way to preserve carotid blood flow during and after ECMO. Reconstruction of both the subclavian artery and jugular vein can be done in the majority of patients using these techniques and may prevent long-term neurologic sequelae.

Quantum Leap Forward in the Management of Cardiac Trauma: The Pioneering Work of Dwight E. Harken

Panagiotis N. Symbas, MD, and Alexander G. Justicz, MD

Department of Surgery, Division of Cardiothoracic Surgery, Emory University School of Medicine, Atlanta, Georgia

Doctor Dwight E. Harken made numerous contributions to the field of cardiac surgery, and in particular the management of cardiac missiles. A few highlights are reviewed.

"If . . . history teaches us anything, it is that man in the quest for knowledge and progress, is determined and can not be deterred."

John F. Kennedy, 1962

FOREIGN BODIES IN, AND IN RELATION TO, THE THORACIC BLOOD VESSELS AND HEART

I. Techniques for Approaching and Removing Foreign Bodies from the Chambers of the Heart

DWIGHT E. HARKEN, M.D., Lieutenant Colonel, M.C., A.U.S., Brookline, Massachusetts

When compared with the history of surgery in general, the field of cardiac surgery is young, and has evolved almost entirely within the late nineteenth and particularly the twentieth century. This has not been a completely gradual, incremental process. Rather, it has been a time when periods of quiescence have been interspersed with episodes of explosive development, discovery, and initiative. To take the analogy of evolution one step further, this can be regarded as a process similar to "punctuated equilibrium" in which the relatively stable mainstream of cardiac surgery is interrupted with sporadic introductions of new surgical techniques, instrumentation, and technological advances [1]. When viewed within this context, Dwight E. Harken's article entitled "Foreign Bodies in Relation to the Thoracic Blood Vessels and Heart," which was published in 1946, represents a quantum leap forward in the development of cardiac surgery [2]. At a time when progress in cardiac surgery was slow, his contributions to the field inspired an entire generation of younger surgeons, and challenged the establishment to reevaluate its position regarding surgery on the heart. In the words of Blatchford and Anderson [3], Harken's report amounted to a surgical tour de force.

Background

Interest in penetrating injury to the heart and great vessels precedes recorded history. Hippocrates [4] recognized that cardiac wounds were inevitably lethal, and Aristotle [5] wrote that "the heart alone of all viscera cannot withstand serious injury." The overall pessimism engendered by these founding fathers led to a fatalistic approach to cardiac injuries until well into the eighteenth century. Actually, there had been some thought on the part of Hollerius [6] as early as the sixteenth century that injury to the heart might be survivable. The proof came in 1642 when Wolf [7] noted a healed wound in the heart of a deer and Tourby [8] observed the human equivalent at autopsy in a man who had been stabbed 4 years before his death. Despite these clinical observations, progress in the management of penetrating cardiac injuries did not proceed rapidly. In 1709 Boerhaave [9] reaffirmed the widely held belief that all wounds of the heart were mortal.

In reality, however, data were beginning to accumulate in the experimental work of Block [10] in 1882 and deVecchio [11] in 1895 that suture of cardiac wounds in rabbits and dogs was not only feasible but survivable. This fact was elegantly demonstrated by Rehn [12] in 1896 when he performed the first successful human cardiorrhaphy. Dwight Harken himself noted, with some amusement, that Rehn performed his operation in the same year that Sir Steven Paget commented in his text of surgery, "surgery of the heart has probably reached the limits set by Nature to all Surgery: no new method, and no new discovery can overcome the natural difficulties that attend a wound to the heart" [13]. Harken's commentary on this embarrassing literary overstatement serves as a cautionary note to all students of medicine, ". . . do not make myopic predictions. Furthermore, if you feel you have a great idea, do not parade it until you have reviewed the literature" [14].

The first American to perform cardiorrhaphy was L.L. Hill in 1902. He subsequently reviewed the literature and reported several more cases [15]. Numerous reports of cardiorrhaphy followed. The mortality associated with operative management of these injuries, while still high (approximately 60%), was markedly less than that of nonoperative treatment (approximately 90%).

By the end of the third decade of the twentieth century, several myths relating to cardiac injury had been debunked. All cardiac injuries were not lethal, and the majority of patients who survived for clinical evaluation

were candidates for repair. Bigger [16], however, suggested that pericardiocentesis should be used both diagnostically and therapeutically when possible, with operation being reserved as the treatment for unstable patients. This approach was based on the fact that although the heart and great vessels could be exposed and repaired, in so doing the mortality was high and varied widely. Therapy continued to be reactive rather than anticipatory, and a unified, systematic approach to wounds of the heart and great vessels was lacking. Although cardiorrhaphy was an established technique, it was by no means clear that it was ideal for all cardiac wounds, and in some cases it represented considerable overtreatment.

The Work of Dwight E. Harken

Dwight Harken would soon change the status quo. As a young surgeon in training, he had been intrigued by the muscular strength, valve design, and flow characteristics of the heart. He felt inexorably drawn to study its function further, and in doing so, noted a marked resistance on the part of his mentors to manipulate the heart: "I wondered about the reluctance of these master surgeons to touch it. It seemed incomprehensible that we surgeons who are considerably mechanically oriented should not attack this significantly mechanical organ" [14]. Harken was quite aware, however, that the potential risks of cardiac procedures in the early 1940s were prohibitive, and he confined his ardor for more aggressive cardiac interventions to the laboratory. "To enter this formidable field, I had to find a disease that was absolutely and always fatal. The disease must be positively, absolutely diagnosable, preferably at an early stage; such was subacute bacterial endocarditis" [14]. As a true clinical scientist, he created an animal model of bacterial endocarditis and a cardioscope with which he could look into the beating heart to resect vegetations. Had it not been for the intercession of World War II and the development of penicillin, we would have undoubtedly seen more of this technique.

During World War II Harken was called to duty in the military corps, where he became a consultant thoracic surgeon in the European theater. It was here that he observed shell fragments and other missiles in human hearts. This was a quintessential case of opportunity meeting the prepared mind. Drawing on his prior experience, Harken theorized that foreign bodies should be removed from the heart and great vessels for the following reasons: (1) to prevent embolus of the foreign body or the associated thrombus, (2) to reduce the incidence of bacterial endocarditis, (3) to avoid recurrent pericardial effusions, and (4) to diminish the danger of myocardial damage with subsequent rupture or myocardial aneurysm [2].

In characteristically measured fashion, he consulted with other leading surgeons of the time and discussed these indications. The result was a consensus that the cardiac missiles should be removed. Over a period of 10 months, Harken removed 78 missiles that were within or in proximity to the great vessels. Three of these were embolic. In addition, he extracted 56 foreign bodies from

the heart, 13 of them from the cardiac chambers. Citing the size and location of the missiles as being critical factors in treatment, Harken also categorized foreign bodies that should be left undisturbed. In so doing, he demonstrated the consummate judgment that allowed him to operate on 134 patients without a single death. It is a testament to Harken's surgical intuition that these indications have undergone only modest revision despite the vast changes in the field of cardiac surgery since that time [17]. Several technical aspects that he used then deserve emphasis. First, he routinely opened the pleura at a time when most surgeons were obsessed with extrapleural approaches. Second, every attempt was made to avoid "dislocation" of the heart during manipulation. In addition, the epicardium was kept moist with a procaine hydrochloride solution. Fourth, stitches were placed over the palpated foreign body and were used both to maintain hemostasis during the removal and to secure a pericardial patch later. Finally, the pericardial sac was opened into the pleural space to avoid postoperative cardiac tamponade. These, in addition to numerous other contributions, helped change the field of cardiac surgery and secure Harken's name in surgical history.

Conclusion

When one considers the relative sophistication and technological advancements of the late twentieth century, it is easy to forget the initiatives and developments that have led to the state of cardiac surgery today.

Attribution of credit for great contributions seems to depend on some uneven balance of timing, relevance to current clinical problems, originality, technical skill, and perseverance. As one reviews the rapid development of modern cardiac surgery with these criteria in mind, Dwight Harken's work on "foreign bodies in, and in relation to, the thoracic blood vessels and heart" is truly a landmark in the history of cardiovascular surgery. He was the first to document safe and successful approaches to the removal of cardiac foreign bodies. Moreover, Dr Harken broke down many of the boundaries of fear surrounding the practice of surgery on the heart, thereby laying the groundwork for the many other subsequent developments in cardiac surgery.

Notice From the American Board of Thoracic Surgery

The American Board of Thoracic Surgery began its recertification process in 1984. Diplomates interested in participating in this examination should maintain a documented list of the operations they performed during the year prior to application for recertification. This practice review should consist of 1 year's consecutive major operative experiences. (If more than 100 cases occur in 1 year, only 100 need to be listed.) They should also keep a record of their attendance at approved postgraduate medical education activities for the 2 years prior to application. A minimum of 100 hours of approved CME activity is required.

In place of a cognitive examination, candidates for recertification will be required to complete both the general thoracic and cardiac portions of the SESATS IV syllabus (Self-Education/Self-Assessment in Thoracic Surgery). It is not necessary for candidates to purchase

SESATS IV booklets prior to applying for recertification. SESATS IV booklets will be forwarded to candidates after their applications have been accepted.

Diplomates whose 10-year certificates will expire in 1995 may begin the recertification process in 1993. This new certificate will be dated 10 years from the time of expiration of the original certificate. Recertification is also open to any diplomate with an unlimited certificate and will in no way affect the validity of the original certificate.

The deadline for submission of applications is May 1, 1993. A recertification brochure outlining the rules and requirements for recertification in thoracic surgery is available upon request from the American Board of Thoracic Surgery, One Rotary Center, Suite 803, Evanston, IL 60201.

Technical Advances in the Treatment of Left Ventricular Aneurysm

Noel L. Mills, MD, Charles T. Everson, MD, and David R. Hockmuth, MD

Department of Surgery, Cardiology Center, New Orleans, Louisiana

The resulting abnormal geometry after surgical treatment of left ventricular aneurysm has concerned a number of surgeons since the first successful repair in 1958, but little attention was placed on the altered geometry until attempts were made to effect a more physiologic aneurysmorrhaphy in 1973. Substantial attention was focused on a concept of geometric reconstruction from within the left ventricle in 1985. A prosthetic patch was employed with the concept to redirect normal muscle bundles to their original orientation and position. Further refinements include use of improved materials for the repair, preservation and bypass of the left anterior descending coronary artery, ablation of ventricular arrhythmias when indicated, and the absence of prosthetic material

used in contact with the pericardial surface. Our experience with repair of 61 left ventricular aneurysms at West Jefferson Medical Center over a 4½-year period with a 3.3% mortality rate has prompted a change from the standard linear repair to routine use of a modified endoventricular repair. Currently, the low surgical risk due to advances in left ventricular aneurysmorrhaphy combined with the knowledge that contractile areas will progressively deteriorate in ventricles stressed by poor hemodynamics and with data showing improved left ventricular function postoperatively have led to more liberal recommendations for early left ventricular aneurysm repair.

(*Ann Thorac Surg* 1993;55:792-800)

Patients with left ventricular (LV) aneurysms that occur after myocardial infarction do not form a homogeneous population. The actual incidence depends upon one's definition of LV aneurysm. In this review, the definition of LV aneurysm is that of a postinfarction aneurysm of the left ventricle that is a consequence of transmural scar with dyskinesia (paradox) of the LV motion. The entity occurs in 10% to 35% of patients who have had a transmural myocardial infarction. Schlichter and co-workers [1] reviewed pathologically proven LV aneurysms and found that the natural history involved a 27% survival at 3 years and a 12% survival at 5 years. Proudfit [2] reviewed angiographically proven LV aneurysms and found a natural history that involved a 5-year survival of 47% and 10-year survival of 18%. The difficulty with the definition of LV aneurysm in the literature is evidenced by the variation in the survival of patients with LV aneurysm; the most favorable report of patients treated nonsurgically showed a 5-year survival as high as 70% [3].

The adverse effects of LV aneurysms depend upon the extent of muscle damage, the size of the dyskinetic area, presence of clot, arrhythmias, the extent of coronary disease, and the amount and functional quality of the remaining LV muscle. The results of surgical repair are related to the magnitude of the geometric effects on the remaining left ventricle. These adverse geometric effects are not only secondary to the loss of contractile tissue in the area of the aneurysm but are due to the increase in LV size and volume. The increase in the size of the LV cavity

increases wall stress and increases myocardial oxygen demand as dictated by Laplace's law. Using Mirsky's [4] modification of Laplace's law, the largest cross-sectional wall tension at the equator of the ventricle or circumferential wall stress may be calculated. Circumferential wall stress and thus the myocardial oxygen consumption are found directly proportional to LV dimensions. Evolution of the principles of LV aneurysm repair now make it mandatory to correct not only the mechanical problem secondary to the failed cardiac physiology but also the atherosclerotic lesions resulting in ischemia of the remaining functional areas of the heart.

Indications for Operation

Congestive Heart Failure

The reasoning offered for surgical repair of LV aneurysms that result in congestive heart failure is based on the principles outlined in the previous paragraph. There may be an additive effect of ischemia secondary to coronary atherosclerotic lesions in the remaining coronary vessels.

Emboli

Another clear indication for repair of LV aneurysms is systemic arterial emboli, many of which may be "silent." One half of patients with LV aneurysms who undergo operation or autopsy have mural thrombi [1, 5]. It is our contention that when transmural infarction has resulted in stasis and endocardial injury with the formation of irregular mural thrombi, there is rarely, if ever, a true healing with fibrosis or neoendocardium over such thrombi.

Address reprint requests to Dr Mills, Department of Surgery, Cardiology Center, 4500 Wichers Dr, New Orleans, LA 70072.

Arrhythmia

When myocardial ischemia coexists with ventricular irritability, patients with an LV aneurysm may have development of automatic ventricular arrhythmias. A reentrant rhythm may occur when two or more electrically heterogeneous pathways are connected proximally and distally. An impulse arriving at a distal connection may return by the initially blocked pathway. If the originally blocked site recovers excitability, the impulse may reenter the circuit. Operative excision is a therapeutic option for a reentrant ventricular tachycardia. Patients with ventricular arrhythmias and coexistent ventricular aneurysms are candidates for mapping and excision of the reentrant circuit at the time of ventricular aneurysm repair. Programmed electrical stimulation at the time of cardiac catheterization identifies sustained ventricular tachycardia as life-threatening. The responsible ventricular tissue can be identified [6].

There is controversy concerning the necessity of studying with pharmacologic testing and mapping all patients who have ventricular aneurysms. There is a definite trend at this time to perform such preoperative testing because such a large number of people in this country have postmyocardial infarction "sudden death."

Angina

The myocardial ischemia in the patient with an LV aneurysm is aggravated by increased wall tension. Angina may be the major symptom in a patient with an isolated ventricular aneurysm when the oxygen demand exceeds its supply. According to Wynne and associates [7], a periischemic "border zone" with weak contractions has been described surrounding the nonischemic muscle.

Concomitant atherosclerosis in the coronary arteries of noninfarcted myocardial bed will accentuate the degree of angina.

Size and Rupture

Even though aneurysms may progress to an enormous size, frank rupture of an established aneurysm is rare. As a homeostatic defense mechanism, the body calcifies the area of paradox. Occasionally, the aneurysm may expand and progress to erode through the diaphragm or into pulmonary structures. Other factors permitting, a large aneurysm is an indication for operation.

Mitral Insufficiency

Mitral valve regurgitation in association with an LV aneurysm—an unwelcome finding even when standing alone—carries a significant increase in operative mortality if secondary to papillary muscle involvement by the infarction [8]. Rarely will an associated coronary revascularization reverse mitral valve insufficiency secondary to scarred papillary muscles in these patients. Valve repair or replacement can often be accomplished through the opened ventriculotomy used for aneurysmorrhaphy.

Impairment of Nonaneurysmal Myocardium

The *global* ejection fraction is a standard method used to numerically quantify the ability of the heart to eject.

However, the *contractile* ejection fraction of the noninfarcted area of a heart with an LV aneurysm is more useful, because it evaluates the function of the nonaneurysmal muscle mass. The presence of an LV aneurysm, especially involving more than 25% of the LV surface, burdens nonaneurysmal myocardial fibers and ultimately decreases the contractile ejection fraction. This phenomenon of LV stress is not too dissimilar from the problem of aortic valvular insufficiency, in which patients are seen to change from an acceptable ejection fraction with an acceptable operative mortality to an inordinately low ejection fraction with an almost prohibitive operative mortality within a time frame of as little as 1 year. Although some authors have advised repair of LV aneurysms only if medical measures fail [9, 10], a more current understanding of the pathophysiology has led clinicians to advise repair before such "irreversible changes," secondary to progressive impairment of nonaneurysmal muscle by increased wall tension, if an acceptable mortality rate can be achieved by the surgical team [11].

Anatomical and Physiological Notes

The normal heart has an elaborate architecture with fibers and muscle layers moving in different directions. The formation of an LV aneurysm distends and enlarges the ventricular cavity, grossly distorting the directions of the muscle fibers. In the presence of an aneurysm, the aneurysmal area of the ventricle expands during systolic contraction. A portion of the forward flow stroke volume is actually "stolen" when an LV aneurysm involves more than 10% of the ventricular surface, causing shortening limits of the remaining myocardial fiber to be exceeded. The ventricle dilates and stiffens, stroke volume decreases, and the end-diastolic pressure increases [12] (Fig 1).

With enlargement of the LV cavity, tangential pressures on the heart wall must be higher to exert acceptable arterial blood pressure. The surgeon, ideally, should attempt to reshape the LV cavity in such a way that muscle bundles are brought toward their original orientation (Table 1).

Treatment

In 1881 the cause of LV aneurysm was determined to be secondary to myocardial infarction [13]. By 1922, LV aneurysms were identified by roentgenography [14], but not until 1951 could an LV aneurysm be diagnosed angiographically [15]. Treatment of LV aneurysm has classically included medical therapy, surgical repair, and cardiac transplantation. Small aneurysms with no clot and no elevation of the LV end-diastolic pressure should be followed up medically with noninvasive techniques if the patient is asymptomatic. Aneurysms may become quite large as they "mature" after myocardial infarction. However, in our experience, there is no aneurysm that is "too large," especially if the patient does not have mitral insufficiency. If the papillary muscles are not involved, there is always "enough remaining ventricle" to sustain

Fig 1. Left ventricular (LV) function in systole and diastole of the normal heart and the heart with LV aneurysm. Note the LV cavity length (A to A') shortens and the size (B and B') decreases with systole. When an LV aneurysm has developed, the cavity length (A to A') and size (B to B') increase during systole. (LAO = left anterior oblique; RAO = right anterior oblique.)

adequate cardiac output, and even hearts with massive aneurysms may be surgically repaired [8]. Patients with asymptomatic moderate-sized LV aneurysms with a global ejection fraction of 0.55 or greater and a normal contractile ejection fraction may be treated medically if the patient has no serious coronary disease. However, when the contractile ejection fraction is less than 0.50, the risk of deterioration is great and the patient should be considered for operation unless the aneurysm is small. Even with more extensive LV damage, many seemingly "hopeless" cases may be successfully treated with aneurysm repair when the contractile ejection fraction is 0.25 to 0.30 if the mean pulmonary artery pressure is less than

Table 1. Effects of Left Ventricular Aneurysm

% Ventricle Involved	Clinical Effect
10%	Decreased ejection fraction
15%	Increased LVED pressure, increased LVED volume
20%	Left ventricular enlargement
25%	CHF
>25%	Myocardial fiber shortening limits are exceeded
40%	Shock

CHF = congestive heart failure; LVED = left ventricular end-diastolic.

Fig 2. Standard linear ("sandwich") repair of a left ventricular aneurysm where point A is sutured to point A' to a variable distance on the ventricular septum. The geometry of the heart is inappropriately reconstructed as the remaining functioning left ventricular cavity is reduced in size and the lateral wall and medial (septal) wall are sutured together at a point that they would normally be separated by several centimeters. The left anterior descending coronary artery is occluded by sutures. (LV = left ventricle; RV = right ventricle.)

40 mm Hg and the cardiac index is greater than or equal to $2.1 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ [11]. If there is an associated cardiomyopathy due to a cause other than ischemia, a poor outcome may be expected. Clearly, transplantation should be performed as a treatment of choice when the contractile ejection fraction is less than 0.25 and when there is right ventricular dysfunction, permanent mitral insufficiency, and poor target coronary arteries for bypass.

Repair of Left Ventricular Aneurysm

In 1944, Beck [16] described his attempt to plicate ventricular aneurysm using fascia lata. Modern surgical treatment, however, has been attributed to Likoff and Bailey [17], who in 1955 performed a closed resection of an LV aneurysm using a special side-biting clamp through a thoracotomy incision.

Linear Repair

In 1958, Cooley and colleagues [18], using cardiopulmonary bypass, performed the first successful aneurysmectomy using a buttressed linear suture line. This "standard linear repair" is still the most common repair used today (Fig 2). A linear repair of the heart is usually carried out using felt strip buttresses to "sandwich" the closure as a leak-proof repair.

A primary closure with sutures through the fibrous base of the aneurysm, and closure using absorbable polyglycolic acid strips to reinforce the linear repair, are modifications of that technique. Each avoids the use of prosthetic material on the surface of the heart which may become infected, erode into pulmonary structures, or present technical problems if reoperation is necessary. A major disadvantage of this conventional repair is that the lateral and medial (septal) wall of the left ventricle are sutured together at a point where they would naturally lie several centimeters apart, thereby significantly decreasing the functional LV cavity size and distorting the natural LV

Fig 3. The Stoney repair of left ventricular aneurysm was an early attempt to increase the curvature of the ventricular segments. The lateral myocardial wall is advanced down the ventricular septum to the junction of scar and healthy muscle. (LV = left ventricle; RV = right ventricle.)

geometry (see Fig 2). There is no exclusion of septal paradox when the septal area is significantly involved.

Plication

Generally, cardiac surgeons plicate ventricular aneurysms during cardiopulmonary bypass in association with coronary artery grafting when considerably less overt scar than was anticipated from preoperative angiograms is found at the time of operation. In one study, plication was a factor that did not significantly affect long-term survival of patients after aneurysm repair [19]. Generally, plications are reserved for small scars in patients who do not have serious LV dysfunction and elevation of the LV end-diastolic pressure. One real hazard of using the technique of plication is that of missing an intraventricular clot attached to the endocardium and causing its embolization by the plicating sutures.

Geometric Reconstruction: Early Attempts

Hutchins and Brawley [20], in 1980, reported 18 patients who died after repair of ventricular aneurysms. In studying the human left ventricles, a method for estimating ventricular functional activity of the heart at autopsy was described by applying a modification of Laplace's law. A curvature thickness index correlated with the pressure-producing activity of the heart was used to study the influence of cardiac geometry on the results of operation. Hutchins and Brawley noted that reduced curvature thickness indexes in patients with postoperative shock appeared to arise as a result of ventricular reconstruction that reduced ventricular wall curvature. This important study was the first to suggest that LV function after LV aneurysm resection could be improved by altering the standard repair to a more favorable geometry. Hutchins and Brawley specifically noted that the repair for LV aneurysm, as described by Stoney and associates [21], was preferable as it increased the curvature of the ventricular segments. The repairs by the Nashville group were carried out by advancing the lateral myocardial wall down the ventricular septum to healthy myocardium (Fig 3). They noted an improvement in the LV end-diastolic pressure in 50% of patients. Adequate size of the remain-

ing ventricular cavities and clinical improvement in the majority of the 29 patients were also reported. Stoney and associates did specifically comment that no attempt was made to revascularize the left anterior descending coronary artery.

Daggett and associates [22] also were troubled by deformity of the ventricular cavity. The introduction of their external patch technique for ventricular reconstruction in patients undergoing inferior wall infarctectomy was another milestone in the surgical treatment of LV aneurysms. Komeda and associates [23] reported their early work, which began in 1982, of using an "inverted T closure" of the left ventriculotomy as an attempt to restore a more normal conical shape to the left ventricle. The operative mortality was statistically less than that of conventional repair ($p < 0.01$). However, the "inverted T closure" patients were operated on later in the study when the team had more experience and their overall surgical technique had improved (Fig 4).

Endoventricular Repair

Jatene [24], in 1985, introduced the concept of geometric reconstruction of the left ventricle using prosthetic patch material. Ventricular dysfunction after "sandwich" repair of ventricular aneurysms with Teflon felt strips had been found by his group to lead to varying degrees of ventricular dysfunction. He noted the maldirection of normal spiral muscle bundles after infarction and ventricular aneurysm formation with bundle distortion in the transverse as well as longitudinal direction [5]. His theory is to redirect the normal muscle bundles as much as possible to their original position and orientation to induce a reduction of the ventricular diameter and a shortening of the ventricular cavity in systole. The basic concept is to reshape the LV cavity in such a way that it resembles an

Fig 4. Inverted T closure of left ventricular aneurysm has been reported in an attempt to restore a more conical shape to the left ventricle. Buttressed sutures are used and the left anterior descending coronary artery is included in the suture line.

Fig 5. Jatene techniques (endoventricular circular plasty): (A) Septal distortion or bulge is first addressed by plication with horizontal sutures. (B) The aneurysmal mouth is circumferentially constricted by pursestring suturing to avoid the distorted geometry of a linear repair. (C) Prosthetic material is used to oversew this area. (D) When the aneurysm is large, and direct suture would produce inordinate ventricular distortion or suture tension, a Dacron patch is sutured to the mouth of the aneurysm. These techniques leave considerable material exposed to the pericardial cavity.

infarcted left ventricle in which distention of the infarcted area did not occur. Palpation of the myocardial thickness is used to identify the area to be obliterated. The first step in Jatene's technique is to tailor the left ventricle toward an oval cavity. This is carried out by placing one or two pursestring sutures at the transition from normal to fibrous tissue on a beating heart. The pursestring sutures are placed around the orifice of the aneurysm so that the orifice can be brought down to a size estimated to be close to that of the original infarcted area of left ventricle. Septal dysfunction is also addressed by a septal plication. The concept is to prevent an elongation of the orifice with approximation of the fibrous rim as occurs in the standard linear repair. A direct suturing of the aneurysm is then carried out if the size seems adequate. If not, a ventricular patch is used to complement the closure (Fig 5). It is this accomplished surgeon's opinion that operating with the heart beating makes it much easier to decide on proper suture placement. The Jatene technique, however, involves a sizable amount of prosthetic patch material and felt surface strips that reinforce the margins of the repair, all of which are exposed to the pericardial cavity. A postoperative infection of such material from a sternal infection or otherwise will present a formidable problem. Adhesions from external prosthetic material are troublesome should reoperative coronary artery bypass grafting ever become necessary. Hospital mortality was decreased from 11.6% to 5.8% after changing to his current technique of LV reconstruction.

Dor and associates [25], since 1984, have used circular patch techniques for LV reconstruction and have named their techniques "endoventricular circular plasty." Like Jatene's technique, the septal akinesis, as well as the remaining paradox of the left ventricle, is excluded. The methods of repair used by Dor's group have been reported to result in superior hemodynamics [11, 26]. Left ventricular reconstruction is carried out using a pericardium-covered Dacron patch. A more complex operation may be performed, wherein an endocardial flap of scar, which is hinged on the septum, is mobilized with a 3- to 4-cm radius. It is then sutured superiorly, laterally, and inferiorly. The left anterior descending coronary artery is spared and is bypassed whenever possible. A distinct disadvantage of the technique is that the repair, which is buttressed with felt, is left open. A circular suture is necessarily placed around the margins of the cut ventricle to control bleeding. A theoretical disadvantage of the endoventricular flap technique is that the flap, which is fashioned of scarred myocardium, may develop paradox in the late postoperative period. The patient follow-up with that method has only been approximately 1 year. Although the concept of having an autogenous lining for the left ventricle is appealing, emboli from prosthetic LV patches have not been reported (Fig 6). More recent experience with 207 patients and a 6.2% mortality was reported by Dor and associates [26] at the 72nd Annual Meeting of the American Association for Thoracic Surgery in Los Angeles on April 24, 1992. Uncertainties were

Fig 6. Dor techniques (endoventricular circular plasty): (A) A Dacron patch lined with pericardium is sutured circumferentially at the junction of scar and normal muscle. The excess lateral aneurysm is excised, and the repair is left open. (B) Autologous endocardial patch technique. Reconstruction is carried out by developing a septal hinged flap of scar that is then sutured circumferentially around the remaining mouth of the aneurysm.

mentioned concerning size of the patch, quality of the patch, and mitral insufficiency. Dor and associates concluded that their technique is feasible for LV aneurysm in any location, that it excludes all akinetic areas, and that it improves LV function to a stage that exceeds the theoretical contractile ejection fraction.

The endoventricular technique described by Cooley [27] is simplified by no excision of aneurysm tissue and by the use of an elliptical woven Dacron patch sutured to the inside of the left ventricle at the proper area as described by Jatene and Dor. His repair is called "ventricular endoaneurysmorrhaphy." The left ventricular closure on the surface of the heart was initially carried out using polyester felt strips for reinforcement. An intervening cavity that fills with clot is allowed to occur. Both Dor and associates [26] and Cooley [28] have abandoned the technique of allowing prosthetic material to remain in contact with the pericardial cavity. Komeda and associates [23] mentioned the use of autologous pericardium or a glutaraldehyde-preserved bovine pericardium for repair of acute LV aneurysms and have reserved Dacron graft material for chronic LV aneurysms. The difficulty with suturing Dacron graft is mentioned in their report. The long-term effects of pericardium subjected to LV pressure is unknown. Endoventricular patch repair achieved a statistically significant survival over conventional repairs in patients with severe LV impairment (ejection fraction < 0.20).

Endoventricular Repair With Felt Patch

We have modified the above-mentioned techniques, yet maintaining the basic geometric philosophy that improves LV function. After lysing adhesions, opening and decompressing the LV, and carefully removing any thrombus, we bypass coronary arteries. Cold fibrillation to 25°C is preferred to cardioplegia if there is no major LV hypertrophy or aortic insufficiency upon manipulation of the heart. The heart is defibrillated temporarily every 20 minutes. A thick nonporous Teflon (USCI, Division of Bard Cardiovascular, Inc, Billerica, MA) felt oval patch that has been soaked in antibiotic solution is used for the endoventricular repair as it conforms more readily and securely than stiff Dacron patch material to the irregular trabeculated endocardial surface of the left ventricle. Usually, some resection of dense trabeculae at the muscular-scar junction is required to allow a smoother coaptation between the patch and ventricle. The patch material has a velour-like surface, which enhances a firm attachment of fibrous tissue and neoendocardium. Continuous 2-0 polypropylene over and over suture is used to suture the patch to the "mouth" of the aneurysm. The suture line is interrupted at three to four points, as a tear anywhere along the course of a solitary suture line would likely result in failure of the repair. The surface of the heart is then closed with a continuous double-run polypropylene suture without any foreign material exposed to the pericardial cavity. The left anterior descending coronary artery (LAD) is spared and bypassed whenever possible to afford some degree of increased blood supply to the upper septal areas and diagonal branches (Fig 7). For repair of posterior ventricular aneurysms, the technique is essentially the same except that the patch is triangular rather than oval. Not only can arrhythmogenic endocardial foci and scar be excised, but also the mitral valve may have a concomitant annuloplasty procedure or replacement when indicated. The advantages of this modification are as follows:

1. LAD is preserved and can be bypassed.
2. Thick felt readily conforms to the irregular LV trabeculated wall.
3. Felt is considerably easier to suture than stiff woven Dacron.
4. No prosthetic material is in contact with the pericardial surface.
5. Favorable LV geometry is maintained.
6. Covering (neoendocardium) on LV felt patch has been tested and proven secure by use in prior cardiac procedures.

There has been one report of an experiment on 6 domestic pigs in which a Dacron patch was inserted to simulate an LV anterior apical aneurysm. The authors of that report concluded that patch ventriculoplasty was of no greater benefit than linear repair [29]. The work was refuted in a letter to the editor by Dor and co-workers [30], in which they pointed out that the experimental model cannot be compared with postinfarction LV aneurysms in humans because such patients have a slow change in

Fig 7. Modified endoventricular repair of a left ventricular aneurysm: After removal of the clot and, if necessary, excision of irritable foci, an oval endoventricular Teflon felt patch is sutured at the "red/white junction" circumferentially around the mouth of the aneurysm with 2-0 polypropylene continuous suture. The appropriate geometry of the heart is maintained as opposed to use of the linear "sandwich" repair. Patch size is determined using the size of the mouth of the aneurysm and the degree of left ventricular dilatation as guidelines. The size of the patch approximates the size of the left ventricular infarcted area if dilatation, paradox, and aneurysm did not occur. Septal paradox is relieved with this technique, as opposed to the standard linear repair (top insert). As shown in the bottom insert, the ventriculotomy is closed longitudinally without prosthetic material, and clot is allowed to form in the obliterated cavity. A concomitant coronary bypass graft is performed to the left anterior descending coronary artery. There is no felt contact with the pericardial surface.

ventricular global geometry and regional curvature. Increases in LV end-diastolic volume, loss of muscle mass in areas of the infarction, and hypertrophy of the remote myocardium are all secondary changes that occur in patients with left ventricular aneurysm.

Two clinical reports compared linear and endoventricular repair. Cooley [28] studied 24 patients postoperatively after endoventricular repair and found 71% had improved ejection fraction from a mean of 0.277 preoperatively to a mean of 0.368 postoperatively ($p < 0.01$). The outcome for patients who underwent repair by conventional techniques (103 historical controls) were 51% improved, 15% worse, and 26% unchanged. Endoaneurysmorrhaphy resulted in 76% improved, 6% worse, and 18% unchanged.

In a retrospective study flawed by a nonrandom statistically insignificant sample, Kesler and associates [31] compared the effectiveness of linear closure (40 patients)

and circular closure (22 patients) as techniques to repair LV aneurysms. Two-dimensional echocardiograms were available for comparison in 29 linear and 13 circular closure patients postoperatively. The circular technique was performed as described by Jatene. Three of the linear closure group had plications. Ten of 22 patients needed no patch. Kesler and associates observed no significant difference between the two techniques. Analysis of clinical results with three-dimensional evaluation techniques such as multiplane echocardiography, gated computed tomography, or magnetic resonance imaging might have assisted in determining whether differences in function and geometry of the techniques had been present. In any event, the small sample size greatly limits the usefulness of the study.

Skeletal Muscle Reconstruction

In 1966, Petrovsky [32] reported the use of the diaphragm to reinforce LV repairs. A logical extension of this work in light of advances in the field of dynamic cardiomyoplasty was reported in 2 patients by Magovern and associates [33] in 1987. The latissimus dorsi muscles were used to cover large LV aneurysmal defects. They were electrically trained to contract during systole using a dual chambered atrioventricular sequential bipolar pacemaker. Reconstructed fibrous endocardial tissue provided the inner layer of the repair. Both patients improved from congestive heart failure to normal activities. Ejection fractions were improved with stress in both patients in the late postoperative period when the pacers were switched from the off to on mode. Further work is needed to put this operative approach in proper perspective in relation to indications and patient selection (Fig 8). This has also been investigated by Carpentier and associates [34].

Left Anterior Descending Revascularization

Classic techniques using the linear closure of LV aneurysms involve the suturing closed of the LAD for antero-lateral aneurysms, unless some residual aneurysm is left in place. More often than not, bypass to the LAD is feasible in patients with LV aneurysm. In patients with multiple areas of distal LAD atherosclerotic disease the disease has developed simultaneously throughout the LAD and some collateral circulation has usually occurred, offering protection from aneurysm formation with LAD obstruction. This is in contrast to patients who experience a sudden occlusion of a proximal LAD lesion with very little distal LAD disease. An LV aneurysm more often develops in the latter survivors. After studying early and late determinants of survival after LV aneurysm repair, Rizzoli and associates [35], in 1988, insisted on a revascularization of the LAD. A report on LV aneurysms from the Montreal Heart Institute [36] noted a favorable outcome influenced primarily by revascularization of residual territory of the LAD. The authors of that report also emphasized that an improved survival rate with that philosophy was reported by Atkins [37] and by Najafi and co-authors [38]. Cooley [27] mentioned that any resection of aneu-

Fig 8. Repair of a large left ventricular aneurysm with a paced left latissimus dorsi through a second rib window. Fibrous endocardial tissue is used as the inner left ventricular lining covered by the muscle flap. A standard atrioventricular sequential bipolar pacemaker is used with the sensing leads implanted on the right side of the heart. The bipolar pacing leads are placed proximally and distally on the latissimus dorsi flap.

rysmal surface should be done on the ventricular free wall side instead of the septal area to avoid suturing or occluding vessels from the LAD in the interventricular septum. Before our change in basic technique, we reported a 5-year survival of 88% in patients undergoing ventricular aneurysm repair who had a concomitant internal mammary artery graft to the LAD. The 5-year survival of patients having a saphenous graft to that vessel was 72%. When no graft was placed to the LAD system in the course of LV aneurysmorrhaphy, the 5-year survival dropped to 65%. Because of the small number of patients, the beneficial effect of internal mammary artery grafting as opposed to saphenous vein grafting could not be statistically demonstrated. Also, there is a tendency among cardiac surgeons to avoid use of the internal mammary artery graft in older, sicker patients in whom the primary objective is to get such patients successfully through what may be a serious operation. Of the overall 246 patients reported, 55% had an LAD graft, indicating a philosophy of offering revascularization to perianeurysm myocardial mass with marginal blood supply to enhance postoperative ventricular function and survival of the early postoperative stress of operation [20]. Theoretically, this approach may decrease postoperative ventricular arrhythmias and has varied from earlier experience as

reported in 1977 [39]. Dor and associates [26], in updating their experience, emphasize use of internal mammary artery grafting (85% of 207 cases) of the LAD in antero-lateral LV aneurysm repair.

Cardiology Center Experience

In the period from July 1, 1987, through December 31, 1991, 61 patients had repair of LV aneurysms on our service at West Jefferson Medical Center. The average age was 56.6 years. There were 44 male and 17 female patients in the group. Concomitant coronary bypass grafts included an average of 3.06 grafts per patient. Fifty-four aneurysms were anterolateral, and there were seven inferior aneurysms in the group. Thirty-five patients had bypass to the LAD in conjunction with their anterolateral aneurysm repair. Internal mammary artery grafts were used in seven instances. Initially endoventricular repair was used only sporadically; however, it has been used in our last 22 consecutive patients.

There were two hospital deaths in the group (3.3%). A 70-year-old woman was transferred to West Jefferson Medical Center in congestive heart failure receiving amiodarone who had ventricular arrhythmias. She had LV aneurysm repair, mitral valve replacement, and coronary artery bypass with an intraaortic balloon pump and died of a low cardiac output syndrome. There has been one death in the last 49 patients (2.0%). That patient, a 42-year-old blind, diabetic man on chronic dialysis with cor bovinum, had a preoperative ejection fraction of less than 0.20 and pulmonary hypertension to 80 mm Hg. He had a ventricular aneurysm repair and three concomitant coronary bypass grafts. After an initially gratifying response, he had sudden death during endotracheal suctioning on the first postoperative day.

Since March 1989, the majority of patients have had preoperative testing for ventricular arrhythmias at the time of cardiac catheterization and, when indicated, excision of irritable foci during the time of aneurysm repair. All patients, except 1 who had preoperative electrophysiological testing, have been studied postoperatively and have had no serious ventricular arrhythmias requiring drug therapy. The 1 patient required an automatic implantable cardioverter defibrillator. There has been one late death secondary to ruptured mitral valve chordae tendineae and chronic pulmonary disease.

There has been considerable change in LV aneurysm surgery since the surgical attempts for treatment of this entity in the early years of cardiac surgery. Mortality rates since 1972 have ranged up to 20% with a mean mortality of $9.4\% \pm 5.2\%$. When combined with other cardiac procedures, the mortality rate ranges up to 23% with a mean of $11\% \pm 5.6\%$ [40]. The statement that aneurysm repair should be carried out only if medical measures fail has been appropriately challenged as cumulative survival rates have been reported. Better postoperative LV function at rest and during exercise has been found in patients who had LV aneurysm repair with an endocardial patch instead of those who had a standard linear repair [28, 41]. A clear technical trend from plication or excision to repair

incorporating an endoventricular technique with preservation and bypass to the LAD has occurred.

The acquisition of new knowledge in thoracic surgery is a continuum. Ideas and practices may change significantly as a result of experience, but there have been limited ways to communicate easily the reasons for such modifications.

The purpose of this section is to present brief follow-up reports from authors whose work was previously published in *The Annals of Thoracic Surgery*. The goal is to learn whether the

original conclusions have stood the test of time, and whether or not previously recommended techniques have been modified, replaced, or discarded. Contributions to Update are short progress reports that do not preclude subsequent, more complete articles.

1992: Effect of Internal Mammary Artery Dissection on Sternal Vascularization

Michel Carrier, MD, Jean Grégoire, MD, François Tronc, MD, Raymond Cartier, MD, Yves Leclerc, MD, and Louis-Conrad Pelletier, MD

Departments of Surgery and Nuclear Medicine, Montreal Heart Institute, University of Montreal, Montreal, Quebec, Canada

Internal mammary artery (IMA) dissection may cause sternal devascularization and ischemia resulting in sternal wound complication. To evaluate the effect of median sternotomy and IMA dissection on sternal vascular supply, sternal bone tomography was performed 7 days and 1 month after cardiac operation in 67 patients. Seventeen nondiabetic patients had single IMA grafts, 18 had double IMA grafts, and 12 had only saphenous vein grafts or valve replacement. Twenty diabetic patients were studied after any one of these operations. Seven patients were restudied 1 month after the operation. Sternal technetium-99m-methylene diphosphate tomography was performed. The sternum was visualized and focal zones of hypoactivity represented sternal hypoperfusion. The ratio of hypoactivity area over total sternal area was calculated for every patient. After median sternotomy without single or double IMA grafts, the

averaged hypoperfusion ratio was $4\% \pm 1\%$ compared with $13\% \pm 3\%$ after single IMA grafts and $24\% \pm 6\%$ after double IMA grafts ($p < 0.0001$). Diabetic patients without IMA, with single IMA, and with double IMAs showed hypoperfusion areas of $5\% \pm 3\%$, $15\% \pm 5\%$, and $23\% \pm 9\%$, respectively, a result similar to that of nondiabetic patients. One month after operation the hypoperfusion area decreased to $2\% \pm 2\%$ ($p < 0.05$) in restudied patients. Our results indicate that IMA dissection causes a significant although partial and temporary sternal ischemia, which is more severe after double IMA than single IMA mobilization and which may be incriminated in the development of sternal wound infection. This vascularization defect was not greater among patients with diabetes mellitus.

(*Ann Thorac Surg* 1992;53:115-9)

1993 Update: Michel Carrier, MD, Jean Grégoire, MD, Raymond Cartier, MD, Yves Leclerc, MD, and L. Conrad Pelletier, MD

Department of Surgery, Montreal Heart Institute, Montreal, Quebec, Canada

In a previous report [1], bilateral dissection of internal mammary arteries had been shown to cause partial and temporary devascularization of the sternum in the immediate postoperative period. This sternal ischemia could play a role in the increased incidence of wound complications when both mammary arteries are used for coronary artery bypass grafting. Recently, the inferior epigastric artery has been suggested in coronary artery bypass grafting as an alternative to saphenous vein grafts. In the experience reported by many authors, the inferior epigastric artery graft was associated with bilateral mammary artery grafts to obtain complete myocardial revascularization. Despite early clinical success, Barner and associates [2] described sternal and abdominal wound

Fig 1. Ratio of hypoperfused to total sternal area 7 days after operation (mean $\pm$ standard error of the mean). There is no difference between groups. (IEA = inferior epigastric artery; IMA = internal mammary artery.)

Address reprint requests to Dr Carrier, Department of Surgery, Montreal Heart Institute, 5000 Belanger St East, Montreal, Que H1T 1C8, Canada.

Fig 2. Ratio of hypoperfused to total sternal area 1 month after operation (mean $\pm$ standard error of the mean). There is a significant ($p < 0.05$) difference between groups. (IEA = inferior epigastric artery; IMA = internal mammary artery.)

complications in 2 patients who underwent inferior epigastric artery grafting.

Because the epigastric arteries are a source of collateral blood flow to the ischemic sternum after bilateral dissection of internal mammary arteries, the dissection and harvesting of epigastric arteries might increase sternal ischemia and the risk of wound complication after operation. The objective of this follow-up report is to evaluate the effect of dissection of bilateral mammary and epigastric arteries on sternal vascularization and wound healing.

Sternal bone tomography was performed 7 days and 1 month after bilateral mammary artery grafting with or without unilateral epigastric artery grafting in 22 patients. Sternal technetium 99m-methylene diphosphate tomography was performed. The total sternal area was delineated, and focal zones of hypoactivity representing sternal hypoperfusion were identified. In each patient, the ratio of the number of pixels in hypoactive areas to total sternal area was calculated.

Thirteen patients with bilateral internal mammary artery grafts were compared with 9 patients with bilateral mammary grafting associated with unilateral inferior epi-

gastric artery graft. Patient age and preoperative clinical and angiographic characteristics were similar in both groups. Seven days after operation, the average sternal hypoperfusion ratio was $18\% \pm 6\%$ after bilateral mammary artery grafting compared with $24\% \pm 8\%$ after epigastric and bilateral mammary grafting, a nonsignificant difference (Fig 1). One month after operation, the average hypoperfusion ratio in patients who underwent bilateral mammary artery grafting averaged $3\% \pm 2\%$ compared with $13\% \pm 5\%$ after epigastric and bilateral mammary artery dissection, a significant difference (Fig 2). No sternal wound complication was observed in either group of patients.

Our results indicate that unilateral epigastric with bilateral mammary artery dissection causes significant although partial and temporary sternal ischemia. Although not more severe, the hypoperfusion lasts longer when the epigastric artery mobilization is added to bilateral internal mammary artery harvesting. Adding epigastric artery dissection to bilateral mammary artery grafts could therefore increase the ischemic effect and the resulting risk of wound complication. Although the use of the inferior epigastric artery is gaining in popularity [3, 4], the indications are not yet well-defined. Our results suggest that bilateral mammary and epigastric artery grafting should probably be avoided when other risk factors for wound complication such as diabetes mellitus, chronic obstructive pulmonary disease, obesity, and advanced age are present.

Thoracic Surgery Directors Association: 1992 in Review

Nineteen ninety-two was a year of increased activity and rejuvenation for the Thoracic Surgery Director's Association (TSDA). The Executive Committee—Drs Martin F. McKneally, President, Gordon F. Murray, President-Elect, Mark B. Orringer, Secretary-Treasurer, and Sidney Levitsky and Stanton P. Nolan, Executive Committee—began to refocus the Association on current issues important to our mission as educators and advocates of our residents. With the stimulus provided by the American Association for Thoracic Surgery (AATS) Retreat held at Snowbird, Utah, in September 1991, the TSDA continued the introspective evaluation now underway in our specialty, particularly in regard to resident education.

At the February 1, 1992, TSDA meeting in Orlando, Florida, the Association heard reports that paralleled the major topics discussed at the AATS Snowbird Retreat: Drs John Waldhausen on Cardiothoracic Resident Education; Andrew Wechsler on Cardiothoracic Research; Frank Spencer on the Cardiothoracic Surgeon and Social Responsibility; William Gay on Funding of Cardiothoracic Research; and George Magovern on the Scope of Cardiothoracic Surgery.

After a discussion of these presentations, a decision was made to plan a symposium on Alternative Approaches to Thoracic Surgical Education at the next TSDA meeting. Further, the idea was born that the TSDA and the Association of Program Directors in Surgery might begin to establish a dialogue to further discussions about the length and content of the thoracic surgery residency education curriculum. Doctor Ben Wilcox, Chairman of The Society of Thoracic Surgeons Ad Hoc Committee for Graduate Education, announced plans for a consensus conference on thoracic surgery residency education for Fall 1992. In an effort to provide a more fair and organized selection process for general surgery residents applying to thoracic surgery residency programs, a National Thoracic Surgery Resident Matching Program, endorsed by the TSDA Executive Committee, the American Board of Thoracic Surgery (ABTS), and the Residency Review Committee for Thoracic Surgery was enforced, and 84 of the 90 eligible residency programs (93%) were registered for the Match at the time of the February 1 meeting. In response to the proliferation of industry-supported courses being offered to thoracic surgery residents without specific documentation of their educational value, a Committee on Extramural Educational Programs chaired by Dr Stanton Nolan was appointed to develop a process for defining TSDA-approved resident education programs and the appropriate process for funding such programs in accord with the guidelines published on December 3, 1990, by the counsel on Ethical and Judicial Affairs of the American Medical Association regarding gifts to physicians from industry.

At the two TSDA meetings held in Los Angeles, California (April 25 and April 27, 1992), several important issues were discussed:

1. A successful Match for thoracic surgery resident selection for 1994 was completed in April 1992, with 93% of eligible programs participating. Of the 132 available residency positions in these programs, 123 (93%) were filled through the Match. Of the 183 residency applicants who participated in the Match, 123 (67%) matched; there were 60 (33%) unmatched applicants who applied for thoracic surgery residencies. Participation in the Match is now a condition for membership in the TSDA.
2. Doctor Ben Wilcox, Chairman of the ABTS, announced that at the April 1992 meeting, the Board voted to change its membership representation to include two representatives from the TSDA. This change is viewed as a substantial step in strengthening the efforts of both the ABTS and the TSDA.
3. Because of the October 1989 decision of the ABTS to no longer accept for the certifying examination candidates trained in Canadian programs (effective for residents beginning their training July 1, 1992), the TSDA Executive Committee recommended a Bylaws change that would give Canadian Program Directors Associate Member status (rather than severing ties with the Canadian Program Directors). Discussion of this recommendation is ongoing.

A symposium on Alternative Approaches to Thoracic Surgery Residency Education was held at the April 25, 1992, meeting and included the following five presentations:

1. "Is certification in general surgery essential for the practice of cardiothoracic surgery in the 1990s?"—Randall Griepp.
2. "The ideal general surgery curriculum for entry into thoracic surgery residencies—the blended program"—Sidney Levitsky.
3. "The case for the traditional two-year thoracic surgery residency"—Mark Orringer.
4. "The integrated Hopkins model"—Bruce Reitz.
5. "The current structure of general surgery—bearing the gold standard"—Gordon Murray.

After discussion of these presentations, there was a general consensus about the need to better define the components of the curriculum both in General Surgery and Thoracic Surgery residency education. The TSDA looks forward to receiving the report of the Joint Conference on Graduate Education in Thoracic Surgery held in

Oak Brook, Illinois, in September 1992. That report will be the focus of the next TSDA meeting in January 1993.

On October 10, 1992, in New Orleans, during the meeting of the American College of Surgeons, the TSDA Executive Committee met informally with officers of the Association of Program Directors in Surgery and the Chairmen of their respective Residency Review Committees to initiate a dialogue about improving the curriculum for residents planning careers in thoracic surgery. The ultimate goal of these and future such meetings is to ensure that the specialty of thoracic surgery is involved

early in the teaching of our future trainees and that it exerts a steering effort on their programs while they are in general surgery residency. The task before us is to define the important components of the thoracic surgery curriculum so that we can have a starting point for negotiations with our general surgery counterparts. This will be the mandate of the TSDA Committee on Curriculum and Education chaired by Dr Andrew Wechsler.

REVIEW OF RECENT BOOKS

Near Misses in Cardiac Surgery

By Myles Edwin Lee, MD

Stoneham, MA, Butterworth Heinemann, 1992

146 pp, \$29.95

Reviewed by John H. Calhoon, MD

Doctor Lee has collected a summary of some 40 cases encountered during his practice. Easily readable completely in two to three hours, this text reviews a number of sand traps in the fairways of thoracic surgery. Doctor Lee had the misfortune of finding these traps and subsequently extricating himself with a minimum of penalty. Covered in these vignettes are how to deal with difficult redo procedures, the ill-prepared surgical patient,

the misinformed medical colleague, cardiopulmonary bypass disasters, and a variety of looks at aortic dissections. As I gleaned these pages, I couldn't help but feel that his case studies would be enlightening to the surgical resident, the young cardiac surgeon preparing for a board examination, or the most seasoned of thoracic surgery practitioners. Although a number of the cases may be a review of bad experiences for most, it was my strong feeling that there is something in this book for everyone. His discussions of each problem were brief, yet sage and complete. I found the book highly enjoyable. I think it is appropriate reading for all who practice cardiovascular surgery.

San Antonio, Texas

Venting and Deairing Without a Roller Pump

To the Editor:

It was refreshing to read the article on simple and safe technique for left ventricular venting by Lundy and associates [1]. "Standard" techniques that suck away blood and air using roller pumps under varying levels of negative pressure from varying locations are accepted without critical evaluation. These should result in cellular trauma and carry added risk of infection due to admixture with room air.

We have adopted the following venting and deairing procedure, with a desire to make it as gentle as venous return and avoid expenses due to a vent suction line incorporating a pump [2, 3]. A cannula is inserted into the left atrium and connected to the venous return line. Before cardiotomy the blood in the lesser circulation is drained into the pump. During bypass in patients whose mitral valve is competent and interatrial septum is intact, such as in tetralogy of Fallot, ventricular septal defect, and left ventricular outflow obstruction, the vent is kept open and keeps the field dry, minimizing the need for cardiotomy suction. In others, the vent is temporarily clamped. After repair is completed the vent is reopened and drains initially air and blood and later only blood into the venous line. The left ventricle is gently squeezed after making the mitral valve incompetent by distorting it by external pressure.

In patients with grossly dilated left ventricle or in whom aortic leak is anticipated, the vent is advanced into the left ventricle to keep it unloaded as long as necessary in addition to serving as an air vent. In patients undergoing redo open mitral valvotomy, we believe it is unnecessary to free the adhesions and release the left ventricle [4]. To deair and decompress the left ventricle, we advance the vent into the apex of the left ventricle, which is tethered anteriorly. A malleable wire inside the vent catheter helps to mold the catheter into a suitable curve and retains it in situ [3].

In patients whose left heart is not opened (bypass operations) the vent is inserted into the main pulmonary artery and connected to the venous return. We have found hardly any need to suck blood away from the coronary arteriotomy.

This method has the following advantages. There is "gentle" venting and deairing and less trauma. It is economical because a vent pump circuit is not necessary. It can be maintained as long as necessary, and keeps the left ventricle unloaded.

Measurement of Instantaneous Pulmonary Capillary Blood Flow

To the Editor:

In 1971, *The Annals* published the work of Greenberg and associates [1], in which instantaneous pulmonary capillary blood flow was measured with the nitrous oxide (N_2O) method using a pneumotachograph (nonplethysmographic method or airway volume change method) in surgical patients. Their work was also quoted in the *Handbook of Physiology* [2] in 1987. I believe the method they used in that study deserves some comment.

If an N_2O body plethysmographic method is used for the measurement of pulmonary capillary blood flow, the box flow meter should show inward gas flow into the box as the pressure in the box decreases due to N_2O absorption [2]. Likewise, Greenberg and associates [1] assumed that if an N_2O -pneumotachographic method is used, there will be inward gas flow into the airway as alveolar gas pressure decreases due to N_2O absorption by pulmonary capillary blood. Accordingly, the gas flow tracing during breath holding on air was subtracted from that after N_2O inhalation to derive the capillary flow.

I used an N_2O -pneumotachographic method to obtain the pulmonary capillary blood flow, from which pulmonary artery systolic storage volume fraction could be measured in anesthetized patients. The pneumotachograph was connected to the airway (endotracheal tube) in such a way that the outward gas flow produced positive or upward waves. Surprisingly, there was no inward gas flow into the airway during apnea on air or after N_2O inhalation. Instead, there was an outward pulsatile gas flow during apnea both on air and after N_2O inhalation, and the gas flow after N_2O inhalation was lower than that on air, suggesting that the gas flow after N_2O inhalation was attenuated due to N_2O uptake by pulmonary capillary blood flow as shown in Figures 1 and 2. In Figure 2, to obtain a whole cycle of pulmonary capillary blood flow wave, the gas flow tracings

Fig 1. Pneumotachograph gas flow recordings in an anesthetized patient. The gas flow tracing after N_2O inhalation was superimposed over that on air during apnea. (This study was approved by the Institutional Review Board.) (ECG = electrocardiogram; PAP = pulmonary artery pressure; PCBF = pulmonary capillary blood flow; PCG = phonocardiogram.)

Fig 2. A whole cycle of pulmonary capillary blood flow wave tracing (not smoothed). (ECG = electrocardiogram; PCBF = pulmonary capillary blood flow.)

within the interval of two R waves of the electrocardiogram were averaged, and the gas flow tracing after N_2O administration was subtracted from that on air.

My observation is consistent with the findings of the previous study by Wasserman and Comroe [3]. The gas flow (Krogh spirometer volume) tracing after inhalation of N_2O was smaller than that after inhalation of air, and subtracted from the tracing after inhalation of air to derive pulmonary capillary blood flow.

It is not clear why the pattern of the gas flow in the study by Greenberg and associates [1] is different from that in my study or others'. Because the pulsatile gas flow during apnea is produced by the pulmonary capillary pulsation, the gas flow during apnea both on air and after N_2O inhalation should be an outward flow. Thus, one cannot subtract the gas flow tracing on air from that after N_2O inhalation, because the gas flow tracing after N_2O inhalation is smaller than that on air. Reexamination of this point is warranted.

Surgical Management of Spontaneous Pneumothorax in Patients With AIDS

To the Editor:

Doctor Fleisher and associates [1] have published an excellent article on surgical treatment of spontaneous pneumothorax in patients with acquired immunodeficiency syndrome (AIDS). Recently, we had occasion to treat an AIDS patient with recurrent bilateral pneumothorax, as a consequence of aerosolized pentamidine prophylaxis, which required surgical treatment to resolve.

In the last 2 years the administration of aerosolized pentamidine in patients infected with human immunodeficiency virus (HIV) has become general practice as a prophylaxis against *Pneumocystis carinii* pneumonia [2]. At the same time there have been more and more reports of atypical relapses of upper-lobe *P. carinii* pneumonia with the development of parenchymatous cavitation, bronchopleural fistula, and subsequent pneumothorax [3], no doubt due to the poorer distribution of the drug in the lung apices and in the peripheral areas [4]. In fact, it is accepted that if pneumothorax develops in one of these patients, this opportunistic infection should be suspected [5].

Our patient initially required thoracic drainage, but because of persistent air leakage through the drainage system surgical treatment was indicated. A right axillary thoracotomy was carried out, with resection of the apical bullous complex. Forty-eight hours after operation the patient exhibited contralateral pneumothorax, which was treated by drainage but also required operation due to persistent leakage. After 6 months, the patient remains asymptomatic.

For these patients, we recommend thoracic drainage using a water-sealed closed system, with or without aspiration, as an initial treatment. When air leakage persists for more than 8 days surgical treatment is indicated. In cases of bilateral pneumothorax, when operation is indicated we believe—along with other authors [1, 6]—that median sternotomy is the access route of choice.

This case illustrates that although aerosolized pentamidine is effective as a prophylaxis against *P. carinii* pneumonia, it is not free from untoward side effects. Because of the effects described, we believe that in the future the administration of pentamidine with the patient in a supine position should be considered, and the efficacy of other drugs such as cotrimoxazole, dapsone, or pyrimethamine for these patients should be appraised. Also, we should acknowledge the contribution of videothoracoscopy, a technique used in our service in 5 patients with pneumothorax (1 of whom was HIV-positive) since January 1992, with completely satisfactory results.

Reply

To the Editor:

We read with interest Dr Albort and colleagues' letter regarding the surgical management of bilateral spontaneous pneumothoraces in a patient with AIDS. Because a left spontaneous pneumothorax developed in their patient after a right thoracotomy for treatment of a right spontaneous pneumothorax, they recommend a median sternotomy as the incision of choice for the management of these patients.

We reported our initial experience of spontaneous pneumothorax in AIDS patients in 1988 [1]. One patient required a left thoracotomy with stapling of cysts and an apical pleurectomy for a recurrent pneumothorax with a persistent air leak. In addition, this patient had a small right apical synchronous pneumothorax noted on chest roentgenogram, which was treated with closed tube thoracostomy. He was discharged, but readmitted shortly after with a large right pneumothorax, which eventually required a right thoracotomy. At the time, we questioned whether patients requiring operation for synchronous pneumothoraces would be best treated with a median sternotomy and a single bilateral procedure.

The recent advent of video-assisted thoracic surgery has changed our opinion on the possible use of a median sternotomy. We now recommend video-assisted stapled resection of the cystic disease with an apical pleurectomy or pleural abrasion for the treatment of spontaneous pneumothorax in AIDS patients.

Heparin-Induced Thrombocytopenia

To the Editor:

We were quite interested in reading the article by Dr Walls and associates entitled "Heparin-induced thrombocytopenia in open heart surgical patients: sequelae of late recognition" [1]. They reviewed retrospectively patients with heparin-dependent antibodies. Those diagnosed preoperatively did not receive any

further heparin after reversal with protamine sulfate and did not suffer any complications. The group recognized postoperatively had a high incidence of bleeding (53%) and thromboembolic events (44%).

We recently had a similar patient who was known preoperatively to have a heparin allergy diagnosed after a thromboembolic event. Thus the precaution of no further heparin after reversal with protamine was taken. Unfortunately, because of hemodynamic instability, he required an intraaortic balloon pump. Peripheral artery thrombosis and renal failure developed, and the patient died soon after of dysrhythmia from which he could not be resuscitated.

This case illustrates that, unfortunately, knowing beforehand of the presence of a heparin allergy and taking the usual precautions does not prevent the occurrence of thromboembolic complications, especially in the presence of an intraaortic balloon pump.

Lung Cancer in the Young

To the Editor:

We read with interest the report in your journal by Icard and associates [1] and were impressed by the unusually large population of young lung cancer patients. Their data led logically to the conclusion that in young patients with a stage of lung cancer for which surgery is an option, the disease process appears to behave as it does in an older population. However, we cannot accept their implication that lung cancer in young people is not an aggressive form of the disease.

In response to their report, we reviewed our experience at a tertiary care referral center in the United States. We retrieved computerized tumor registry files from the past 15 years (1977 to 1992) and identified 23 patients with bronchogenic carcinoma who were less than 40 years old. Medical records were reviewed for comparison with the parameters evaluated in Icard and associates' report.

Many of our observations agree with those of Icard and associates and with previously published studies [2-4] (Table 1). The male to female ratio, duration of symptoms before presentation, percentage of smokers, and percentage of histologic diagnoses are similar. However, the series reported by Icard and associates is highly selected because patients are referred to their center for operations, and inoperable cases are not admitted. By excluding all patients with stage IV disease, Icard and associates ignore a very important behavior characteristic of lung cancer in young people. Late-stage presentation and therefore inoperability is very common in the young age group, much more common than in the general population. In our series, fully 86% of patients were staged IIb or IV at presentation. This contrasts dramatically with published data on the general population, where late-stage

NSCC = non-small cell carcinoma; WRAMC = Walter Reed Army Medical Center.

presentation (IIb and IV) is markedly less common, approximating 40% of all cases [5].

Icard and colleagues conclude that for young people, "primary lung cancer seems to be related more to the extent of the disease than to a particularly aggressive behavior pattern of the cancer." Although this conclusion is supported superficially by their data, it does not explain the larger question of why cancers in young people so often present in late, inoperable stages.

Although it is possible that young adults present with advanced disease because they remain asymptomatic or ignore symptoms longer, published statistics demonstrate that more than 90% of young lung cancer patients have symptoms at time of presentation [2-4], no different from older people, and that the duration of symptoms at presentation ranges from 2 to 4 months. In older age groups, duration of symptoms before presentation is reported to be at least 4 months [6, 7] and longer even for alarming symptoms such as hemoptysis [8].

Perhaps the favorable experience reported by Icard and colleagues is a result of an unusual referral process or differences in access to medical care compared with other populations studied. This hypothesis is supported by a major difference their report has with the other series, namely, the lower number of symptomatic patients at time of presentation (66% versus 90%).

We concur with the reasoning applied to the data presented by Icard and associates, but we cannot accept their final conclusion. Their work adds important new information to our understanding of the value of an aggressive surgical approach to lung cancer in young people. However, their favorable experience is not shared by their internal medicine colleagues. The fact that most lung cancers in young people present in late, inoperable stages of the disease argues for an aggressive behavior pattern of the cancer.

Reply

To the Editor:

We agree with Drs McCambridge and Eliasson that our population represents a highly selected series because these patients were referred to our center for operations. Our purpose was not to determine the overall prognosis of lung cancer in young patients, which is not possible for a surgical team, but to demonstrate that patients less than 40 years old with resected lung cancer will have a prognosis similar to that of older patients at an equal TNM stage. These results justify our aggressive surgical policy for young patients.

Cervical Esophageal Anastomosis

To the Editor:

I greatly appreciated the interest of Charles D. Fraser and associates [1] in reestablishing the continuity of the cervical

esophagus by a limited local procedure, after a Johnson-type exclusion having a proximal end esophagostomy. I agree with them that whenever possible, a total esophageal substitution should be avoided in these unfavorable conditions created by the previous esophageal perforation. But I disagree with the concept that for a total esophageal exclusion and diversion, the classic esophageal transection is the only currently available technical modality.

A fundamentally new procedure was introduced by Urschel and associates [2] in 1974, using banding to occlude the esophagus below the perforation, combined with side cervical esophagostomy, to avoid the need of a further esophageal replacement.

This type of exclusion was performed successfully (through a laparotomy) in a 9-day-old traumatic lesion [3] after the primary suture of this 15-cm-long tear, with side cervical esophagostomy; in another instance a 6-week-old iatrogenic disruption with right-sided empyema was treated with a similar distal and also cervical banding [4] with tube thoracostomy for suction-lavage. Neither stricture nor need for a late dilation was noted after the subsequent removal of the bands after 10 and 21 days, respectively.

I would like to call attention to the usefulness of this organ-preserving technique, performed simultaneously with the primary repair or after the failure of the initial attempt at esophageal closure. If previously an end-type proximal esophageal diversion has been done, undoubtedly a segmental reconstruction of the esophagus is more advantageous.

Thoracoscopy and Spontaneous Pneumothorax

To the Editor:

With greatest attention we have read the interesting work of Drs Olsen and Andersen [1], and we would like to make the following commentaries.

Based on the high incidence of blebs and bullae in patients with relapsing spontaneous pneumothorax (SP) and on the statistical significance of these as cause of the relapse [2], we elaborated a scheme of treatment of SP that centers around the performance of a thoracoscopy in the first episode [3], like Olsen and Andersen. Thus, between July 1983 and December 1990 we have performed 366 thorascopies, 107 of which were performed in 104 patients with SP, 3 of whom had bilateral pneumothorax that was not simultaneous. Eighty-nine thorascopies were performed for primary or idiopathic SP, and 18 for secondary SP. Patient ages ranged between 15 and 72 years (mean age, 29.4 years); there were 89 men and 15 women.

We always performed the exploration with local anesthesia, and only in 4 cases was sedation added. The local anesthesia

permitted us to perform a Valsalva maneuver to visualize perforated or collapsed bullae or blebs. We classified the endoscopic findings into four types, modifying the classification of Vanderschueren [4]: type I = normal exploration (26 patients; 24%); type II = cicatricial complex apical, single bleb or bulla < 2 cm with or without adhesions (22 cases; 21%); type III = multiple adhesions (7 cases; 7%); and type IV = multiple blebs or bullae < 2 cm, bulla > 2 cm, dystrophie bullae, with or without adhesions (49 cases; 46%); there were 3 cases of lung fibrosis (3%). All these patients have been followed up for at least 18 months. As Olsen and Andersen reported, 80% of the relapses take place before the first year.

All patients with type I SP were treated with aspirative drainage as the only measure. Relapse occurred in 1 of 26 (3.8%); at intervention we found that a plain bulla had passed unnoticed. Of the type II patients 1 was at first operated on and the rest were treated with aspirative drainage. Relapse occurred in 1 of 21 (4.7%); at intervention we found that the bulla was not single but multiple. Of the type III patients 1 was operated on at first and the rest were treated with aspirative drainage. Relapse occurred in 5 of 6 (83.3%). Of the type IV patients, 28 were operated on at first and the rest were treated with aspirative drainage. Relapse occurred in 13 of 21 (62%). The difference in relapse rate between groups is highly significant ($p < 0.0001$).

We agree with Olsen and Andersen that thoracoscopy is an excellent method of selection to guide the treatment of the patients with SP, but we would like to go even further. Probably in all patients with types I and II SP, which is almost half (46%), it is not necessary to add pleurodesis, assuming the minimal relapse of SP shown by our experience. Nonetheless, we should direct all our attention to the patients with types III and IV, to whom we can apply a technique of thoracoscopic surgery assisted by video to realize liberation of adhesions and resection of bullae and blebs with endosuture or laser. We prefer to add mechanical pleurodesis instead of partial pleurectomy for the same reasons given by Olsen and Andersen.

In conclusion, we consider thoracoscopy a useful method of selection for patients with SP, directing them to simple thoracic drainage in types I and II or toward thoracoscopic surgery assisted by video or conventional surgery in types III and IV.

Transplantation Using Donor Hearts From Patients With Circulatory Arrest

To the Editor:

The article by Gundry and associates [1] reported experimental experience in the resuscitation and transplantation of 4 lamb

hearts arrested for 30 minutes after exsanguination. Although the number of experiments is small, this is an interesting study that may eventually lead to an increased number of pediatric donor hearts for transplantation. Whether the same encouraging results could be obtained using adult rather than juvenile hearts remains uncertain.

Based on previous data in the literature, the posttransplantation period of functional assessment of these hearts (of only 30 minutes) may well be inadequate. Ecker and colleagues [2] showed that a 1-hour period of anoxic arrest of the dog heart depressed function immediately and markedly. Although there was a steady improvement in contractility during the initial 2 to 2½ hours after restoration of coronary flow, contractility remained impaired as compared with that of nonischemic hearts. This difference tended to widen in the 72 hours after the ischemic period in spite of complete metabolic and circulatory support.

My own observations in adult dogs, published almost 20 years ago [3-5], would suggest that the mode of death of the animal is a major factor in the potential success of resuscitation. In these experiments the chest was opened and the heart and lungs were isolated from the remainder of the circulation by ligation of the superior and inferior venae cavae and clamping of the aorta proximal to the branches to the head and neck. By isolating the heart and lungs from the rest of the body, acidosis occurring in damaged ischemic organs, such as the liver, no longer affected attempts to resuscitate the heart. The heart, resuscitated by manual massage and defibrillation, supported the coronary and pulmonary circulations only and was relieved of the burden of supporting the entire systemic circulation.

Consistent resuscitation of the *asphyxiated* heart could be obtained after anoxic intervals of up to approximately 30 minutes, but was generally unsuccessful after longer periods. Successful resuscitation was obtained more readily and after longer periods of arrest in the *exsanguinated* (50 minutes) or *electrically fibrillated* (90 minutes) heart. These findings correlated well with those of other studies and, in particular, with those of Lundsgaard-Hansen and associates [6], who, in 1971, found that asphyxia caused much more myocardial damage than exsanguination and that the mode of death was at least as important for the postmortem metabolic state of the heart as the warm ischemic time.

Visual observations made on hearts in animals being asphyxiated or exsanguinated threw considerable light on why asphyxia should be more damaging to the myocardium [5]. Hearts in dogs undergoing anoxic death were forced to attempt to support an entire circulatory workload while functioning in an increasingly hypoxic environment. As the myocardium failed, the chambers of the heart became grossly distended, almost certainly adding to the damage of the myocardium.

Under conditions of exsanguination, however, the blood was being well oxygenated throughout the agonal period. The heart, therefore, was obtaining an adequate oxygen supply until the animal became grossly hypovolemic. Throughout this period, the workload that the heart was being forced to maintain was steadily decreasing as exsanguination continued. By the time the myocardium was experiencing the effects of hypoxia, the circulatory workload was minimal. The heart was at no time put under the adverse conditions met with during death from asphyxia. This was reflected in the absence of distention of any of the chambers of the heart, and also in the fall in maximum time derivative of pressure to only 73% of the control level compared with a reduction to 36% in asphyxiated animals. After resuscitation, very rapid improvement in parameters of left ventricular contractility was recorded in the exsanguinated animals, in

contrast to the slower improvement observed in the asphyxiated group.

In the clinical situation it may be impossible to heparinize the donor's blood before circulatory arrest. There is evidence that circulatory arrest in the nonheparinized subject leads to intravascular clotting, which occludes the small vessels and capillary networks, and this has been shown to lead to greater difficulty in resuscitation of any organ. The experience of Gundry and his colleagues, who achieved good initial resuscitation after flushing the donor heart with a solution that contained streptokinase, is therefore particularly important. The majority of dogs in my own studies were heparinized before the induction of cardiac arrest, but resuscitation was attempted in 5 nonheparinized, asphyxiated hearts, with 3 hearts returning to good cardiac activity after anoxic periods of 20, 40, and 55 minutes, respectively [5].

Reply

To the Editor:

My associates and I are indebted to the pioneering efforts of Doctor Cooper and his colleagues in their attempts to extend the supply of donors for human heart transplantation. As demonstrated in his letter, these efforts began more than 20 years ago, and his results parallel those observed in our experiments in which we successfully reanimated hearts from exsanguinated, dead donors. Doctor Cooper's cautionary notes regarding poor long-term organ function after resuscitation need to be further tested experimentally; however, our own clinical experience using hearts from infants receiving cardiopulmonary resuscitation for up to 1 hour reveal no early or late decrements in systolic or diastolic function, as studied up to 2 years after transplantation [1].

Although our article in *The Annals* only addressed the subject of exsanguinated animals, Dr Cooper also stresses the differences between exsanguinated animals and animals that died of anoxia, suggesting with experimental evidence that the latter makes a much more difficult model for successful resuscitation. We have recently repeated our experiments using an anoxic model of arrest, with a 30-minute waiting period beyond cardiac standstill

for harvest (40 ± 5 minutes after start of anoxia) and using retrograde coronary sinus reperfusion, and have again easily separated all animals from bypass after transplantation [2]. Therefore, we believe that the mode and methods of reperfusion, rather than the mechanisms of death, are the most important factors predicting resuscitation success.

Despite these encouraging findings, it is essential that investigators focus further efforts into defining the ultimate period of warm ischemia that hearts of different ages from various species can sustain and still be successfully reanimated, and whether such hearts will function long-term.

Beneficial Effect of Nicardipine on Perioperative Myocardial Ischemia

To the Editor:

In spite of a dramatic improvement in myocardial preservation techniques, cell damage may still occur during cardiopulmonary bypass (CPB). This can be expressed as postoperative increase in creatinine kinase or as early perioperative electrocardiographically identifiable ischemia. This may be observed in any kind of operation using CPB, although the additional contribution of coronary artery disease and coronary artery bypass grafting operation renders it more problematic. Duration of CPB, graft occlusion, inadequate flow through an internal mammary artery

graft, and ventricular hypertrophy have been shown to enhance the risk of perioperative myocardial ischemia. Whatever the cause, perioperative myocardial ischemia can lead to permanent ventricular dysfunction if not promptly resolved. In the absence of anatomical or technical abnormalities that could be perioperatively corrected, coronary artery spasm and low-reflow phenomenon would be the most probable causes of perioperative myocardial ischemia.

Specific pharmacological treatment could play a crucial role. Nicardipine, a calcium-channel blocker, would appear to be the drug of choice in such a circumstance because of its specific coronary dilating property, its minimal negative inotropic effect (when compared with nifedipine), its potent systemic vasodilatory action, and its inhibitory effect on endothelin secretion. One of us has previously reported the beneficial effect of intracoronary infusion of a large dose of nifedipine in patients suspected of having coronary spasm in the postoperative course of coronary artery bypass grafting [1, 2]. However, the above-mentioned properties of nicardipine and their possible synergetic effect prompted us to use this drug in similar circumstances of perioperative myocardial ischemia when other means were shown to be unsuccessful.

Between February and December 1991, 12 patients with perioperative myocardial ischemia have been successfully treated by intracoronary infusion of nicardipine in our institution. In all cases myocardial preservation has been achieved by the combination of antegrade and retrograde crystalloid cardioplegia (St. Thomas No. 1), topical cooling, and moderate systemic hypothermia (30°C). Patients' characteristics, the onset and degree of ischemia, dose and route of administration of nicardipine, and electrocardiographical evolution are reported in Table 1. The 11 patients who underwent coronary artery bypass grafting showed ST segment elevation in at least one revascularized area. In the patient who received a heart transplant the anterior part of the heart was involved. Six patients displayed severe hemodynamic alteration. The onset of perioperative myocardial ischemia ranged from 1 to 13 minutes after weaning off CPB. The grafts were explored and shown to be patent and nontwisted. Although all the patients were put back on CPB at least once and received nitrates and inotropes, no electrocardiographical improvement was observed. However, ST segment was normalized within a period ranging from 1 to 7 minutes after administration of a 5-mg bolus of nicardipine. Nicardipine administration was usually

Table 1. Nicardipine in Perioperative Myocardial Ischemia

Patient No.	Age (y)	Sex	Procedure	Time of CPB (min)	Onset (min after CPB)	ST segment elevation (mm)	Route	Dose (mg)	Onset of ST normalization (min after NIC infusion)
1	25	F	Heart Tx	130	5	3.0 anterior	AR	5	6
2	64	M	CABG 2 IMA	40	3	2.7 anterior	AR	4	5
3	68	F	CABG 2 SG	45	7	2.0 anterior	SG	5	3
4	76	F	CABG 3 SG	66	4	3.0 anterior	AR	2	2
5	64	M	CABG IMA	35	5	2.9 anterior	AR	5	1
6	76	M	CABG 4 SG	75	3	2.5 inferior	SG	5	3
7	75	M	CABG IMA, 2 SG	69	6	2.0 anterior	AR	5	3
8	71	M	CABG IMA, 1 SG	55	1	1.5 anterior	AR	5	2
9	56	M	CABG 2 IMA	56	13	2.8 anterior	AR	5	7
10	66	M	CABG IMA, GEA	78	4	1.9 inferior	AR	5	3
11	66	M	CABG IMA, 2 SG	75	10	2.5 anterior	AR	5	6
12	61	M	CABG IMA, GEA	67	7	3.0 anterior	AR	5	4

AR = aortic root; CABG = coronary artery bypass grafting; GEA = gastroepiploic artery; IMA = internal mammary artery; NIC = nicardipine; SG = saphenous vein graft; Tx = transplantation.

followed by a short period of deep systemic hypotension and electromechanical cardiac arrest. It is therefore mandatory to administer such a dose of nicardipine during full-flow CPB. When electrocardiographic changes were only observed in a territory revascularized by a vein graft, this was used as a unique route of injection (patients 3 and 6). All patients were subsequently weaned off CPB and had an uneventful postoperative course. No evidence of myocardial infarction has been shown in any of them.

Experimental and clinical data have clearly shown the protective effect of parenteral administration of nicardipine on various forms of myocardial ischemia [3, 4], eg, limitation of myocardial infarction size after coronary artery ligation, prevention and delay of the transient ischemia occurring during percutaneous transluminal coronary angioplasty, and improvement of perfusion in areas chronically ischemic. Our preliminary data strongly suggest that intracoronary bolus infusion of nicardipine could dramatically modify the outcome of perioperative myocardial ischemia after CPB.

This beneficial effect of nicardipine could be explained on several grounds. The inhibition of myocardial adenosine triphosphate breakdown might be crucial immediately after cardioplegic arrest, as the myocardium is restoring energy. The coronary dilating selectivity [4] leads to the enhancement of collateral blood flow, and this could have a beneficial effect on coronary artery spasm. In that respect, although the mechanism of coronary spasm is not known, calcium ions are thought to play a key role in the genesis of spasm [5]. As a calcium-channel blocker with an inhibitory effect on endothelin, nicardipine might counteract the spasm via those two pathways. The low-reflow phenomenon, an impairment of postischemic coronary flow, is an important issue to be addressed. Indeed, one of us has recently provided experimental data indicating clearly that low reflow can be enhanced by coronary dilating drugs with a subsequent improvement of postischemic recovery of cardiac mechanical function after prolonged cardioplegic arrest [6].

In conclusion, we believe that in the presence of perioperative myocardial ischemia without any anatomical cause, nicardipine can be used as the drug of choice as a last resort. We believe that the pharmacological properties of nicardipine could explain an improvement of low reflow and coronary spasm, the most probable causes of perioperative myocardial ischemia when anatomical etiology has been ruled out.

Open Lung Biopsy

To the Editor:

I would like to congratulate Drs Chechani, Landreneau, and Shaikh [1] for finally refuting the last conclusion of Gaensler and Carrington's previously considered landmark article on open lung biopsy. Despite multiple inaccuracies, unfortunately, that study has been considered the "gold standard" for managing patients with diffuse pulmonary disease refractory to medical management [2]. This, misinformation, however, has hampered chest physicians for approximately 30 years.

Doctors Gaensler and Carrington declared that biopsy of the roentgenographically most involved region (usually the lower lobes) in patients with chronic diffuse interstitial lung disease is likely to show meaningless histological findings and that biopsy of lingular and middle lobes should be avoided [2, 3]. These inappropriate conclusions were initially refuted when I reported the results of my study demonstrating the significant sensitivity and specificity of lingular biopsies in patients with similar pathology [4, 5].

Doctor Miller and associates [6] subsequently confirmed our results and then refuted Drs Gaensler and Carrington's conclusions concerning right middle lobe biopsies. Dr Chechani and associates [1] have proven that biopsies of the roentgenographically most involved region are similarly most significant histologically, finally disproving Gaensler and Carrington's last conclusion.

It is imperative that the misinformation espoused by Drs Gaensler and Carrington finally be laid to rest to aid in the resolution of the management of a vexing and extremely important clinical problem. This entity is of added importance to thoracic surgeons, as many patients with diffuse interstitial lung disease are hemodynamically compromised and extremely ill. A surgical approach that is simpler and expeditious while offering a definitive diagnosis is thusly extremely advantageous [4, 5]. With the increasing use of thoracoscopy, biopsy of the lingula or right middle lobe may be somewhat less important but still should be remembered as an approach that satisfies the above criteria for bilateral diffuse pulmonary disease, and is another alternative in the armamentarium of the thoracic surgeon.

Southern Thoracic Surgical Association

Rules for Submission of Abstracts

Abstracts for papers to be presented for the 1993 Annual Meeting are now being accepted. The deadline for postmark of abstracts is May 15, 1993. An original and one copy should be submitted, using the official Association abstract form, to Harvey I. Pass, MD, Chairman, Program Committee, the Southern Thoracic Surgical Association, 401 North Michigan Avenue, Chicago, IL 60611-4267. Additional forms are available upon request from the Association.

Abstracts must summarize an original contribution not presented or accepted for presentation elsewhere. *Abstracts received after the deadline will not be considered.* The information requested at the bottom of this form must be completed indicating who is to receive the notice of acceptance or rejection and who will present the paper if accepted.

Abstracts may be submitted for the regular program, the Forum, or either. Papers selected for the Forum will be published in *The Annals of Thoracic Surgery* if they pass the usual editorial review.

Essayists are reminded that all papers accepted for presentation must be submitted in triplicate to Hendrick B. Barner, MD, Secretary-Treasurer, at the time of presentation or to the Editor of *The Annals of Thoracic Surgery* prior to presentation.

Abstracts frequently obscure the value of their content because they are poorly organized. It is important that methods and results be clearly defined in the abstract; general statements such as "results will be presented" are not acceptable. When a procedure or method is stated to have "advantages," those advantages should be defined. Abstracts that simply summarize results without defining objectives and methods are equally undesirable.

Presentations in the regular program are limited to 10 minutes; those in the Forum are limited to 5 minutes.

In discussion of papers, the Association encourages a healthy spirit of constructive critical review and rebuttal by comments pertinent to the content of the paper being presented. Presentation of the discussion in the form of "secondary papers" will not be welcomed.

INSTRUCTIONS FOR ABSTRACTS

The official abstract form or photocopies must be used. **Authors must indicate whether they want the abstract considered for the regular program, the Forum, or either by checking the appropriate box. Authors must also categorize the principal subject of their abstract by checking the appropriate box.**

1. Title of abstract must be completely CAPITALIZED.
2. Full names of authors must appear on the abstract, without degrees, titles, or appointments.
3. Indicate each author who is a member of the Southern Thoracic Surgical Association with an asterisk following the name.
4. Underline the name of each STSA new member (elected to membership in 1992).
5. Institution or address is to be given.
6. Abstracts must be limited to 200 words and *must be typed double-spaced.*
7. When percentages are used, the absolute numbers of derivation must be stated.
8. The body of the abstract should include:
 - a. A brief statement of the purpose of the study, referring, as appropriate, to the current state of research in the field.
 - b. The methods of study or experimental approach clearly defined.
 - c. A summary of the results and/or conclusions of the study, including sufficient details to support those conclusions.
 - d. A statement concerning the significance and implications of the work.
9. The form must be signed by the principal author attesting that the material will not be presented elsewhere if accepted for the scientific program nor published elsewhere if accepted for publication in *The Annals of Thoracic Surgery*.

CLASSIFIED ADVERTISEMENTS

Classified advertisements for positions wanted or available must relate only to the thoracic or cardiovascular surgical specialties. Display space (minimum, ¼ page) is also available through Art Carlucci, Elsevier Science Publishing, 655 Avenue of the Americas, New York, NY 10010 (telephone: (212) 633-3806; facsimile: (212) 633-3820). All advertisements are subject to the approval of the editor, and material deemed inappropriate for publication in *The Annals* will be rejected. If anonymity is desired, please indicate this at the time of submission and a code number will be assigned. All responses received will remain confidential in the publisher's office and will be conveyed to the advertiser shortly after receipt. The charge for all classified advertising is **\$1.60 per word per insertion, minimum 20 words**. Abbreviations, dates, initials, post office box numbers, telephone numbers, years, and zip codes are considered one word each. **There is an additional fee of \$25.00 per insertion for box number advertisements.** The copy deadline is 7 weeks prior to publication, eg, for the March issue, copy should be received by the 1st of January. Advertisement orders should be for a maximum of 6 months; advertisements may be renewed for up to 6 months at a time. Advertisement copy should be typed double-spaced and mailed in duplicate to: *The Annals of Thoracic Surgery*, Desk Editorial, Classified Advertisements, Elsevier Science Publishing Co, Inc, 655 Avenue of the Americas, New York, NY 10010 (facsimile: (212) 633-3853). Make *nonrefundable* check payable to Elsevier Science Publishing Co, Inc.

Please note that *The Annals* does not function as a placement service and cannot provide information on advertised positions. When answering advertisements, please write individually to each advertiser you wish to contact, using the address given in the advertisement. To respond to an anonymous advertisement, write to Box Number, *The Annals of Thoracic Surgery*, Elsevier Science Publishing, 655 Avenue of the Americas, New York, NY 10010.

SITUATIONS AVAILABLE

Thoracic and cardiovascular surgeon with emphasis on pediatric/neonate cardiac surgery and cardiac transplantation is needed by a full-service thoracic and cardiovascular surgery group on the west coast. Must have ABTS certification. Excellent salary and benefits package. Please respond with curriculum vitae and case list.

Please respond to Box 702. 702K/D

Cardiothoracic surgeon, board certified/eligible, wanted to join established practice in northwest Indiana (very near Chicago). Excellent salary. Please respond with curriculum vitae.

Please respond to Box 723. 723L/G

Thoracic/cardiovascular surgeon: three-man group in suburban New York doing general thoracic and peripheral vascular surgery desires new graduate of approved thoracic program with training in vascular surgery. Please respond with CV.

Please respond to Box 758. 758L/F

Cardiothoracic surgeon, BE/BC, to join busy 1-man private practice in mid-Michigan. Excellent opportunity. Salary leading to partnership. Please send CV and references.

Please respond to Box 779. 779J/C

Thoracic and vascular surgeon, BE/BC, to join active (noncardiac) thoracic and vascular practice in central New Jersey. Please

respond with curriculum vitae and details of experience. Salary leading to full partnership.

Please respond to Box 795. 795K/C

Cardiovascular and thoracic surgeon: Excellent opportunity for a board certified/eligible university-trained surgeon to join a new, growing department in a metropolitan New York community. Academic/private practice setting with excellent compensation. Experience in electrophysiologic surgery, artificial devices, and transplantation helpful. Please respond with curriculum vitae.

Please respond to Box 799. 799L/E

Cardiothoracic and vascular surgeon, board certified, board eligible to join an expanding three-man practice in the Rocky Mountain region. Please send CV and references.

Please respond to Box 802. 802L/E

South of Boston: Two experienced thoracic surgeons in very busy private practice offer employment and partnership opportunity for third. Ideal location 20 miles south of Boston offers educational and cultural advantages of an urban environment with options for country or suburban living. Excellent salary and benefit package, leading to full partnership. If BC/BE, please send CV.

Please respond to Box 805. 805L/E

The Division of Thoracic and Cardiovascular Surgery at the University of New Mexico School of Medicine in Albuquerque is seeking applications for a full-time faculty position at the Assistant/Associate Professor level for July 1993. We are looking for an individual with excellent skills in adult cardiac surgery and with specialized training in cardiac transplantation. The candidate must be board eligible or certified and have strong interest in research and teaching. This is an excellent opportunity for an individual interested in academic achievements as well as a good clinical experience.

Please forward curriculum vitae and three letters of recommendation to Jorge A. Wernly, MD, Chief, Division of Thoracic and Cardiovascular Surgery, University of New Mexico Medical Center-ACC2, Albuquerque, NM 87131. An affirmative action/equal opportunity employer.

809L/C

Cardiothoracic/vascular surgeon: board certified in general surgery and BE/BC in thoracic surgery to join strong cardiovascular practice in western Pennsylvania. Major need for thoracic and vascular surgeon; cardiac surgery if desired. Excellent benefits. Detailed CV must accompany response. All replies treated confidentially.

Please respond to Box 811. 811L/E

Cardiovascular thoracic surgeon—board certified/board eligible and recently trained to join an established, busy, dynamic and expanding private practice in northwest Indiana. The sphere of practice is approximately 30 minutes from downtown Chicago. Guaranteed excellent starting salary with progressive future growth and comprehensive corporate fringe benefit program leading to partnership for the right individual.

Write including CV and details of experience and capabilities to PO Box 3066, Munster, IN 46321. 814A/C

Cardiac surgeon to join established, two-man private practice in Chicago and its suburbs. Salary leading to full partnership. Excellent facilities and experienced associates.

If interested, please respond to Box 815. 815A/C

Experienced and board certified cardiothoracic surgeon needed to join an established group of thoracic and vascular surgeons in a newly approved cardiac surgery program in a community hospital. Responsibilities include coordinating and leading the cardiac surgical team of this group practice. Competitive package.

Please respond to Box 817. 817A/F

Director—Cardiothoracic Surgery: Board certified cardiac surgeon needed to coordinate and direct a new cardiac surgery program in a community hospital in association with an established group of surgeons. Strong community and medical staff support will assure a successful program. Attractive financial package.

Please respond to Box 820. 820A/F

Noncardiac thoracic and vascular surgeon, BE/BC, to join established one-man private practice on Florida's southeast Gold Coast. Send CV and details of experience.

Please respond to Box 822. 822A/C

Cardiovascular surgeon wanted to join three surgeons in an established adult cardiac, thoracic, and vascular surgery practice in north central Texas. Must be board certified/eligible. Salary plus benefits with full partnership available. Please send resume and references.

Please respond to Box 828. 828A/C

Thoracic and vascular surgeon, BC/BE, to join busy, congenial surgical group in Connecticut. Varied and challenging practice at private and university hospitals in close proximity. Excellent salary and benefits with partnership potential. Send CV.

Please respond to Box 839. 839B/E

Cardiothoracic surgeon, BE/BC to join 2-man private practice located in Southeast. Large volume general thoracic, increasing cardiac surgery volume. Prefer recent graduate with training in adult cardiac surgery.

Please respond to Box 840. 840B/G

Cardiovascular and thoracic surgeon to join busy two-man practice of adult cardiac, thoracic, and vascular surgery seeking recent graduate of American training program. Located in beautiful East Texas, surrounded by lakes and national forests—great lifestyle but only 100 miles north of Houston. Well-trained FMGs will be considered.

Please respond to Box 841. 841B/C

Cardiothoracic surgeon: The Miriam Hospital is seeking a cardiothoracic surgeon to join the Department of Surgery, Division of Cardiothoracic Surgery. The individual will function as the Associate Director of this division. The successful candidate must qualify for a full-time medical faculty position at the rank of Assistant or Associate Professor in the Brown University School of Medicine. Minimum requirements include board certification in general and cardiothoracic surgery or eligibility for the latter if training is recently completed. A record of scholarly achievement and national recognition commensurate with the level is expected. A strong clinical background, excellence in patient care and teaching are required. It is expected that approximately one third of the candidate's time will be devoted to teaching. Remaining time will be spent in clinical care and/or administration. The Miriam Hospital is an equal opportunity, affirmative action employer and encourages applications from protected and minority groups. Applications are expected within 6 weeks of the date of this publication. Screening will begin on that date and continue until a successful candidate is identified or the search is closed.

Please forward curriculum vitae or recommendations to A. Gerson Greenburg, MD, PhD, Chair Person, Search Committee, The Miriam Hospital, 164 Summit Ave, Providence, RI 02906. 842B/D

Cardiothoracic surgeon, BC/BE, wanted to join adult cardiac surgery program in the South. Solo practice is very busy serving as regional referral center. First-rate medical facilities, liberal compensation package, and warm hospitality await you! Please send CV.

Please respond to Box 845. 845B/C

Cardiovascular surgeon, board certified/eligible, wanted to join two surgeons in an established cardiovascular program in the southeastern USA. Must have experience in adult cardiac, thoracic, and vascular surgical procedures. Salary/full partnership negotiable. Please send resume.

Please respond to Box 846. 846B/G

BE/BC cardiovascular and thoracic surgeon wanted to join expanding practice in the Southeast area. Full benefit package leading to partnership. Respond with CV and references.

Please respond to Box 847. 847C/H

Cardiothoracic surgeon, board certified with 2 to 5 years experience. Wanted for practice in northeastern United States. Practice currently doing 500+ procedures and anticipates growth of 20%. Preferring surgeon with cardiac, thoracic, and vascular. Salary for 2 years, followed by full partnership. Please respond with CV.

Please respond to Box 848. 848C/D

Retiring or retired cardiovascular surgeon willing to assist only in surgery. No calls.

Please respond to Box 849. 849C

Cardiothoracic surgeon: board certified/eligible, wanted to join well-established, busy practice. Three-surgeon practice. Recent vacancy allows opportunity for the right individual. Available to relocate immediately.

(714) 879-9362. 850C/D

Cardiothoracic and vascular surgeon, board eligible or certified, to join 2-man private practice in Ft. Lauderdale, Florida.

Please send CV to Salem M. Habal, MD, 4800 NE 20th Terrace #107, Ft. Lauderdale, FL 33308; (305) 771-3220. 851C/H

Cardiovascular surgeon, board certified/eligible, wanted to join solo practice in Asheville, NC. Currently setting up a new program. Recent grads preferred but not required. Please send resume.

Dr R. M. Kennerly, 445 Biltmore Ave, Suite 103, Asheville, NC 28801; (704) 258-9446. 852C

The Division of Cardiothoracic Surgery, Saint Louis University, Department of Surgery, is seeking a full-time faculty member. Candidates should be board certified or board eligible and have demonstrated their interest and expertise in teaching, clinical practice, and scientific investigation. Females, minorities, disabled, and veterans are encouraged to apply.

Please send curriculum vitae and bibliography to George C. Kaiser, MD, Division of Cardiothoracic Surgery, Saint Louis University School of Medicine, 3635 Vista Ave at Grand Blvd, PO Box 15250, St. Louis, MO 63110-0250. 853C/H

Pittsburgh—BE/BC cardiothoracic surgeon: Outstanding opportunity to join established 2-person cardiothoracic surgery group affiliated with large teaching hospital. High-volume practice includes comprehensive range of adult cardiovascular and thoracic procedures. Associate will play an active role at main hospital and assist group to develop suburban patient base. Attractive partnership potential.

Please reply to Daniel Stern & Associates, The Medical Center East, 211 North Whitfield St, Suite 240, Pittsburgh, PA 15206; FAX (800) 892-2781 or call (800) 438-2476. 854C/D

Cardiovascular and thoracic surgeon, BE/BC, wanted for an established private practice of cardiac, thoracic, and vascular surgery in the Southeast with potential university affiliation. Initial contact should include curriculum vitae, clinical experience in all three disciplines, surgical results, and references.

Please respond to Box 855. 855C/D

Cardiothoracic surgeon, BC/BE, to join well-established cardiac surgical group in central Florida. Includes adult cardiac, thoracic and vascular surgery. Send CV.

Please respond to Box 858. 858C/E

Cardiovascular surgeon, BE/BC, to join well-established, very busy private practice near Chicago. Recent graduate preferred. Please send curriculum vitae.

Please respond to Box 859. 859C/E

Assistant/associate professor, thoracic and cardiovascular surgery. The University of Wisconsin Medical School Department of Surgery seeks a faculty member in the Division of Thoracic and Cardiovascular Surgery with an interest in a range of clinical, teaching, and research responsibilities. Specialization in thoracic and cardiovascular surgery required.

Applicants should submit resumes by April 1, 1993, to Robert M. Mentzer, MD, Chairman, Division of Thoracic and Cardiovascular Surgery, University of Wisconsin-Madison Medical School, Rm H4/358 Clinical Science Center, 600 Highland Ave, Madison, WI 53792-3236. The University of Wisconsin is an affirmative action/equal opportunity employer. 861C

Coastal Virginia: Thoracic, vascular, general surgeon—board certified by the American Board of General Surgery and board certified or eligible in thoracic surgery to join a two-physician single specialty practice in Hampton Roads. Practice all areas of general vascular and thoracic (except open heart) surgery. Superb network of referrals exists in this rapidly growing community of nearly 300,000. Competitive salary and benefits.

For more information, call or write Kim Georges, Physician Recruitment, 4417 Corporation Lane, Virginia Beach, VA 23462; 1-800-736-8272. 863C/E

Thoracic and cardiovascular surgeon, board certified/eligible, wanted to join five other surgeons in a busy private practice in the Midwest. Practice includes open heart as well as thoracic and vascular surgery. Attractive salary and fringe benefits leading to partnership. Please respond with curriculum vitae.

Please respond to Box 864. 864C

SITUATIONS WANTED

Cardiothoracic surgeon, 35 years old, university trained, board certified with two years busy private practice experience. Seeks opportunity with new program, individual, or group in the Southeast.

Please respond to Box 757. 757J/C

Cardiothoracic surgeon, 32 years old, ABTS certified, in private practice for two years. Good training and experience in all aspects of adult cardiac, peripheral vascular, and thoracic surgery. Seeks

opportunity with an aggressive group practice or new program, preferably in the West/Southwest.

Please respond to Box 857. 857C/E

FELLOWSHIPS

Surgical residents/fellows—Clinical residency/fellowship positions available in adult and pediatric cardiothoracic surgery. Large volume of cases. New Jersey license required. Excellent salary and benefits.

Please contact Lynn B. McGrath, MD, Chairman, Department of Surgery, Deborah Heart and Lung Center, 200 Trenton Rd, Browns Mills, NJ 08015; (609) 893-6611, Ext 359. 653A/C

Cardiovascular surgical fellow: Department of Cardiovascular Surgery, San Francisco Kaiser-Permanente Medical Center, offers a one-year clinical fellowship in cardiovascular surgery beginning July 1, 1993. Applicants must be ABS BC/BE. High volume, excellent salary and benefits.

Please send CV and direct questions to M. Terry McEnany, MD, Chief, Department of Cardiovascular Surgery, Kaiser-Permanente Medical Center, 2350 Geary Blvd, San Francisco, CA 94115; (415) 202-3800. 826A/D

Cardiothoracic surgical fellowship—Allegheny General Hospital is seeking qualified candidates for a one-year, nonaccredited fellowship position in cardiothoracic surgery, available July 1, 1993, through June 30, 1994. The program enjoys a large volume of adult cardiac surgery and thoracic surgery cases, including thoracoscopy, esophageal and pulmonary resections, in addition to a strong research program. The program is assisted by seven physician assistants.

Please send a CV and letters of recommendation to George J. Magovern, MD, Professor and Chairman of Surgery, Allegheny General Hospital and the Allegheny Campus of the Medical College of Pennsylvania, 320 E North Ave, Pittsburgh, PA 15212. 827A/D

Fellowship in adult cardiac surgery beginning 1993 and available for one or two years in private program performing approximately 600 open heart procedures yearly. Cardiac surgery training required. ECFMG and visa-qualified foreign applicants accepted.

Send curriculum vitae to C. Douglas Lees, MD, 22151 Moross Rd, Suite G-20, Detroit, MI 48236. 856C

Fellowship in cardiovascular surgery: Fellowship available in cardiovascular surgery from July 1, 1993, to June 30, 1994, and January 1, 1995, to June 30, 1996, in a large Southeastern teaching hospital. Suitable for individuals waiting to enter or who have completed a thoracic surgery residency. Full training in general surgery required. Please send CV, references, and clinical experience.

Please respond to Box 860. 860C

Heart/lung transplant fellow—for July 1, 1993. One-year medical/surgical fellowship in heart/lung transplantation. Our center evaluates over 100 patients annually and follows more than 150 preoperative and postoperative patients yearly.

Perioperative Care

edited by R.M. Peters and J. Toledo

Current Topics in General Thoracic Surgery Volume 2

1992 480 pages

Price: US \$ 150.00 / Dfl. 240.00

ISBN 0-444-89660-0

The non-surgical care of the patient during surgery is just as important as the care before and after surgery. This multi-authored book encloses the non-surgical care of the patient being prepared for general thoracic surgery, undergoing a thoracotomy, and being cared for during the recovery period. It discusses preoperative evaluation of risk, preoperative preparation of the compromised host, and management of intra-operative fluids, anesthesia and postoperative pain. Comprising additional viewpoints from authors worldwide, this volume covers areas where the presented information could have significant effect on patient welfare and thus help to diminish the incidence of complications during thoracic surgery. Its broad coverage allows the reader access to most of the information needed for effective care of the thoracotomy patient, and includes details of performing cancer surgery on a patient with only one lung.

The book will be of great interest to those involved in general thoracic surgery, namely surgeons, critical care physicians, and chest internists, as well as to directors of cardiothoracic training programs and medical libraries.

function after lung resection (A. López-Encuentra). 2. Preoperative Cardiac Assessment (H.A. Hennein, J.A. Swain). 3. Simultaneous Cardiac and Thoracic Surgery (C. Deschamps, V.F. Trastek, P.C. Pairolero). **Part II. Preoperative Preparation for the Compromised Host.** 4. Preoperative Treatment of Chronic Obstructive Lung Disease (V. Schulz). Discussion (F. Hammond Cole Jr., J.W. Pate). 5. Perioperative Nutritional Management of Thoracic Surgery Patients (K. Moghissi). Discussion (A.E. Baue). 6. Perioperative Management of Hemoptysis (J.R. Benfield, D.P. Link). 7. Thoracic Surgery in the Elderly (C. Ricci et al.). Discussion: Pulmonary resection for lung cancer in the elderly (G. Varela, J. Toledo). 8. The Issue of AIDS for Thoracic Surgeons (J. Allen McCutchan). Discussion (M.J. Wood). 9. Nonspecific and Specific Immune Stimulation in Lung Cancer (J.A. Bennett, M.F. McKneally). 10. Pulmonary

Resection Following Chemotherapy (P. Drings, I. Vogt-Moykopf). Discussion: Pulmonary resection following chemotherapy - perioperative considerations (R.J. Ginsberg, M. Goldberg). **Part III. Immediate Preparation for Thoracotomy.** 11. Physical Condition in Preparation for Thoracotomy (G. Ramos, M. J. Gallo). **Part IV. Intra- and Postoperative Management.** 12. Intraoperative and Postoperative Fluids (R.M. Peters). Discussion (S.R. Dunn). 13. Anesthesia-Specific Problems for Pulmonary Resection (J.L. Benumof). **Part V. Postoperative Management.** 14. Chest Drainage Problems (E. Anyanwu, I. Vogt-Moykopf). Discussion (E.W. Wilkins Jr.). 15. Indications for Re-exploration Thoracotomy (M.J. Milano). Discussion (E.W. Wilkins Jr.). 16. Prevention and Treatment of Atelectasis (R.H. Bartlett). 17. Analgesia Following Thoracotomy (J.L. Benumof). 18. Management of Post-pneumonectomy Empyema of the Pleural Space (J.I. Miller). Discussion (J. M^a. Borro, V. Tarrazona, F. París). 19. Prophylaxis and Treatment of Postoperative Thromboembolism (M. Escribano). 20. Indications for Therapeutic Antibiotics Following Thoracic Surgery (J.W. Pate). 21. Monitoring of Spontaneous Ventilation and Ventilator Support (R.M. Peters). Discussion: Lung and ventilation monitoring (C. Chopin, M. Ribet). 22. Cancer Surgery on a Single Lung (Ph. Levasseur et al.). Discussion: The second primary lung cancer (G.F. Murray). Subject index.

Developments affecting the diagnosis, treatment and prevention of infectious diseases occur frequently and in many fields of study. Staying abreast of these changes is more and more difficult — unless you're a reader of **Infectious Diseases Newsletter**.

Whether you're a physician, nurse, or lab professional, **Infectious Diseases Newsletter** is your remedy for this situation. As a subscriber you will receive brief and to-the-point original articles and case studies covering the latest international news and advances concerning infectious diseases.

A Selection of Recent Articles and Case Studies:

The Resurgence of Tuberculosis, *Charles W. Stratton*.
Group C β -Hemolytic Streptococcal Bacteremia in a Diabetic with Cellulitis, *Robert D. Walsh and Burke A Cunha*.
Fever in the Elderly, *Ricardo A. Barzaga, Natalie C. Klein, and Burke A. Cunha*.
Spread of Multi-Resistant Klebsiella Pneumoniae in Two Chicago Hospitals, *Vincent Idemiyor, Charles E. Cherubin, and Alex Kuritza*.
Tuberculous Pericarditis in an Elderly Male with Lymphoma, *Charles W. Stratton*.

Cardiothoracic Fellow

The Lankenau Hospital and Medical Research Center is a state-of-the-art medical teaching and research facility nestled in a beautiful, yet convenient suburban Philadelphia location. This past year we performed over 800 open heart surgeries including surgery for atrial and ventricular arrhythmias.

We will have a position available July 1, 1993 on our staff for a Cardiothoracic Surgical Fellow. The ideal candidate should be board eligible or certified in general surgery. Board eligible in thoracic surgery highly desired. A Pennsylvania license is a must. Clinical Fellows are welcome to apply.

Along with top of the line technology and professional colleagues, the position offers medical benefits, no city wage tax deducted and a non-smoking environment. For further information, please forward CV to: Dr. Scott M. Goldman, Chief, Division of Thoracic & Cardiovascular Surgery, c/o Personnel Department, 100 Lancaster Avenue, west of City Line, Wynnwood, PA 19096.

A Member of the Main Line Health Family of Hospitals.
An Equal Opportunity Employer

Cardiothoracic Surgeon

The Department of Surgery at the Dartmouth-Hitchcock Medical Center in Lebanon, New Hampshire is searching for an additional academic Cardiothoracic Surgeon at the Assistant/Associate Professor level. Candidates for this position must be BC/BE in Thoracic Surgery and should have demonstrated, by prior training and expertise, superior skills in all aspects of adult and pediatric cardiac surgery as well as general thoracic surgery. The physician will be responsible for the care of patients in an established cardiothoracic practice at The Hitchcock Clinic with privileges extended to the Veterans Administration Hospital in White River Junction, Vermont.

The successful candidate should have demonstrated a commitment to research by previous experience and publications and will have the opportunity for further academic pursuits, including the education and training of medical students and house staff physicians. The individual will be an employee of The Hitchcock Clinic and will receive an appropriate academic appointment as a member of the faculty of Dartmouth Medical School. DHMC is an AAEO employer and is especially interested in identifying female and minority candidates.

Inquiries and resumes should be directed to Charles A.S. Marrin, M.B., B.S., Chairman, Cardiothoracic Surgery Search Committee, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire 03756, (603) 650-7390.

TRENDS IN Cardiovascular MEDICINE

Trends in Cardiovascular Medicine keeps you up-to-date with advances in cardiovascular research that will have important diagnostic and therapeutic implications.

Each issue features six to eight brief reviews of key topics at the vanguard of cardiology. Because clinical advances are often based on experimental observations, **Trends** authors discuss how developments at the lab bench today can influence the practice of bedside medicine tomorrow.

Topics covered by **Trends in Cardiovascular Medicine** include:

Case Studies in Human Genetics

- lipoprotein(a): bridging atherosclerosis and thrombosis
- clinical and molecular genetics of hypertrophic cardiomyopathy
- new insights into genetics of long QT syndrome
- recent advances in viral myocarditis

Emerging Technologies

- the polymerase chain reaction (PCR) and the diagnosis of cardiovascular disorders
- NMR spectroscopy for the study of the biochemistry of the cardiovascular system

Brief Reviews

- strategies for gene therapy using endothelial cell and recombinant animal virus vectors to achieve gene transfer
- new directions in thrombolytic therapy, including the genetic engineering of novel t-PA molecules and other important recombinant proteins
- gender and cardiovascular disease

Trends in Cardiovascular

Medicine's editor-in-chief and executive editors select these topics and their authors, all highly regarded individuals in the area under review. Moreover, all articles are subject to peer-review, ensuring accuracy in presentation.

Trends in Cardiovascular Medicine can help you understand how today's research will change tomorrow's clinical practice.
